COPYING RESTRICTIONS

Reel duplication of the whole or of any part of this film is prohibited. In lieu of transcripts, however, enlarged photocopies of selected items contained on these reels may be made in order to facilitate research.

A Note on the Sources

The pages which were microfilmed for this collection are in generally good condition in the original. There are some pages, however, which due to age are lighter than normal. Additionally, because some volumes are very large and have been bound tightly and cannot be unbound, there are intermittent occurrences of slight distortion of the edges of a small percentage of the pages. We have made every technical effort to ensure complete legibility of each and every page.

THE REDUCTION RATIO FOR THIS REEL IS 16:1

No. 17A. "Magneto Electric Generators"

This scrapbook covers the years 1880-1889 and contains clippings about generators. There are 139 numbered pages.

Blank page not filmed: 139.

The Maxim Electric Light for Marine and other Uses.

In commenting lately (see our issue for July) on the disastrous collisions of two Sound steamboats, and of two ocean steamers which occurred a few days later, we took occasion to remark that these accidents could in all probability have been avoided had the vessels in question been provided with electric signal lights in place of the utterly inadequate oil lanterns with which they were provided. And on the same point we added, that the futility of trusting to these and fog-bells and whistles to avoid collisions, has been demonstrated again and again; while the power of the electric light to penetrate a fog has been shown to be infinitely superior to any form of light yet devised, and its efficacy as a safeguard against this class of accidents is out of all comparison superior to anything else. The use of electric lights should, therefore, be made mandatory on all steam vessels.

We are gratified to have the opportunity at this time of presenting to our readers the illustrations and description of an electric light apparatus specially designed for marine use, and which appears to possess every necessary and desirable feature that an apparatus intended for this special service should have. The apparatus in question is the invention of Mr. Hiram S. Maxim, a well-known inventor of electrical machinery, and is manufactured by the United States Electric Lighting Company, 120 Broadway, New York.

Referring to the accompanying engravings, Fig. 1 represents the electrical generator, or dynamo-electric machine of the Maxim system, and Figs. 2 and 3 show the present form of the electric lamp used with it. The dynamo-electric machine (Fig. 1) is provided with an armature of soft iron rings, with the wire wound parallel to the axis, and so disposed as to permit of the free circulation of air through the armature. This arrangement is designed to prevent the dangerous heating of the generator, which is one of the most serious impediments to the economical use of most of the machines of this class, whether of foreign or domestic manufacture, and is affirmed to answer the purpose very satisfactorily, even with the severe test of running the machine on a short closed circuit.

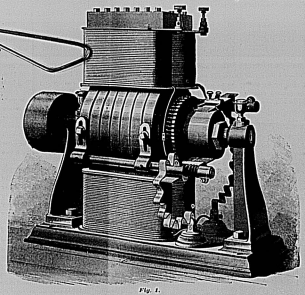

Fig. 1.

The large and heavy commutator has its sections curved in a right and left hand spiral, to avoid the occurrence of a break in the current. The machine is well built, compact and attractive in appearance, and on the score of performance and adaptability for its intended service, will compare favorably with the best machines of its class—a fact which has been amply demonstrated in competitive tests instituted for the purpose of comparing the merits of the several forms of dynamo-electric machines. The inventor has designed a small, high-speed engine for the special purpose of driving the generator directly, without the intervention of belts and pulleys; but the machine may, of course, be driven from any source of power that is available.

Referring now to the lamps, Fig. 2, represents the form of the device intended for use on land or for river steamboats. The details of its construction and operation, will be found below in connection with the description of the lamp shown in Fig. 3, which is more elaborate, and is designed for ocean steamships. In all essentials respecting its working parts, the lamp shown in Fig. 2 is substantially the same. The front, or cover-glass is in strips, to lessen the danger of cracking from the intense heat evolved from the light.

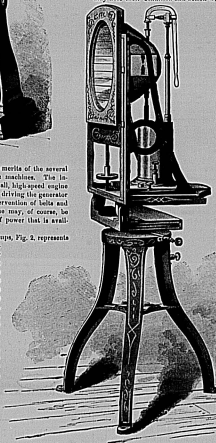

Fig. 2.

Fig. 3 shows the form of lamp designed for ocean steamships. The exterior of the lamp is formed of a strong brass case, cylindrical in shape, mounted on a substantial base piece, and supported on trunnions, so as to be capable of being moved in any direction. Within the case is a silvered reflector of parabolic form, at the focus of which the carbon poles of the electric arc are located. The mechanism of the lamp, by which the position of the carbons in the focus of the parabolic reflector is maintained as they are consumed, is substantially the same as that previously described and illustrated in our October number for 1878, and to which we, therefore, refer those of our readers who wish for details that are not shown in the accompanying engravings. It will suffice to state in this place that the regulating apparatus is perfectly automatic in action, consisting essentially of an electro-magnetic device and appropriate gearing, controlled by the current passing to the lamp. By the action of this regulator, both the carbons are kept continuously in the same place, being fed upward and downward respectively, according to the rapidity of their consumption. This regulator is likewise one of Mr. Maxim's patented inventions.

The lamp may be raised or lowered, or moved forward and backward at will, and the carbon poles may be accurately adjusted in focus by means of regulating screws provided for the purpose. A small lens placed in the side of the reflector throws an inverted image of the carbons on a ground glass screen, so that an observer may note their condition and action without exposing his eyes to their direct glare. The whole apparatus is handsomely finished, and presents a very ornamental appearance. It is enclosed in such a manner that a heavy sea will not interfere with its action. When it is desired to cut off all light in the foreground and to illuminate only distant objects, a funnel-shaped bonnet is attached in the front of the lamp, thus cutting off all light but that emanating from the center of the lamp. It is affirmed that either of these lamps will throw a beam of light strong enough to read by at a distance of five miles on a clear night, and many hundred feet in a dense fog.

The whole apparatus, generator and lamp, seems to possess every requisite and desirable quality for the purpose for which it has been devised, and we feel sufficient interest in the subject of the employment of electric lights on ships—board, to reiterate our previously expressed opinion that in one form or another its use should be insisted on for the prevention of collisions and other disasters that their employment would almost certainly prevent.

Further information respecting this apparatus may be had of the United States Electric Lighting Company, 120 Broadway, New York.

Improvement of the Gramme Magneto-Electric Machine.—Where a continuous current is required, the Gramme machine is in our view not only equal but even superior for purposes such as electric lighting to any other generator of electricity; and this development of the Paccinotti ring has appeared to be in principle and detail so perfect that no inherent defect has hitherto been pointed out. We think, however, that theory indicates a shortcoming which is stated to be of very considerable practical moment, and which will probably be remedied by an invention which will shortly be made public. The distribution of magnetism in the soft-iron ring is very far from being in the direction generally assumed, viz., in the annular direction of the ring itself, which is that in which the inductive effect would be a maximum. The ring being placed between the poles of a magnet, the normal magnetic effect tends to take place in a straight line uniting the poles; and although this direction is considerably modified by the peculiar form of the armature in this case, it is stated that experiment as well as theory indicates that the magnet produced by induction is by no means generated in a line at right angles to the general direction of the wire in the coils upon the ring. The loss of effect from this cause would appear to be considerable; and if this be the case the Gramme machine, as well as others in which a soft-iron ring is employed, may very probably be susceptible of considerable improvement.

AN IMPROVED ELECTRO-MOTOR.*

By THEODORE WIESENDANGER.

While recently many minds have been at work, with more or less of success, to produce improvements in dynamo-generators of electric energy, very few have given their special care and attention to the development of the electro-motor. Experience has taught us hitherto that the efficiencies of one and the same machine by action and reaction, or for use either as a generator, or on the inverted process as an electro-motor, stand in a certain and direct proportion to each other, or that our most efficient generators, such as the Siemens, Brush and Gramme machines prove also the most effective motors, and on the other hand that inferior dynamo-machines invariably are inferior motors. It would, however, be hazardous to conclude from these results that this rule should hold good for all future machines, and from the results of researches I have recently made, I come to the conclusion that the motors which are to supersede those now in use could not be employed as generators. Dynamo-machines, such as now constructed, only prove efficient when their field-magnets are able to retain at all times (*e. g.*, even when the machine stands at rest) a certain and very considerable amount of residual magnetism, and for that reason their cores are made of retentive material, hard cast iron, as is the case in the Brush and Gramme machines; or if the cores consist of soft iron they are attached to large masses of hard cast iron, in such a manner that the latter are inclosed in the magnetic circuit, and form part of the cores.

Generators of the same kind, when made small in size, have cores much larger and heavier in proportion, and, moreover, the baseplate, or, as in the Weston machine, a heavy encasing cylinder, is made to form a portion of the field-magnets. Not all efforts hitherto made to produce efficient small dynamo-machines with cores of soft iron only, have resulted in absolute failure, although men of the highest genius have made repeated and prolonged efforts to solve that most difficult of problems.

These curious facts conclusively prove that the theory explanatory of the action of dynamo-machines, as now universally adopted, viz., the theory of inductive action and reaction between the field-magnets and the armature, can not any longer be considered complete or satisfactory; for even wrought iron—especially when occurring in large masses, always contains an appreciable amount of residual magnetism, more especially after it has once been subjected to strong magnetizations, and if the above theory were correct and complete, then the smallest possible amount of residual magnetism, augmented by repeated action and reaction, would be sufficient for the starting of such a machine in action. This, however, experience proves *not* must be either abandoned or amended.

The inventors of the most recent electro-motive engines have sucked—perhaps unconsciously—upon the idea that the construction and action of electro-motors are based altogether upon the same laws as those of dynamo or magneto machines, and, in accordance with that assumption, the field-magnets of the Desprez motor are made to consist of large and heavy masses of magnetized steel.

Experimenters have also for a long time past clung to the idea that the efficiency of an electro-motor—or the amount of energy to be obtained from such a machine by means of a current of given strength circulating in the coils of its armature only—bears a definite and direct proportion to the magneto-inductive power of its field-magnets, and that an increase of power in the field-magnets alone must necessarily produce greater capabilities of the machine.

This, however, is a mischievous theory, because erroneous in very principle, and development would only lead to the hypothesis of perpetual motion. On the contrary, starting from the consideration of the fact that a very small magnetic needle, if acted upon by one of the poles of another and very powerful magnet, has its polarity destroyed or reversed, and that if one of its poles, say the N pole, is presented to a similar (N) pole of the large magnet, the former will instantly lose its characteristic qualities and be attracted by its overpowering opponent, we can only come to the one rational conclusion that the power of the field-magnets of an electro-motor, as compared to that of the magnet or magnets constituting its armature, should not surpass the limit of some certain ratio, to be determined yet by experiments carefully conducted, and that, if it surpasses the limit, the capabilities of the machine must be impaired. Acting on this principle, I have constructed a motor in which the power of the field magnets is as nearly as possible equal to that of an armature, the core of the former being very light and made entirely of soft iron; and the satisfactory results obtained from this machine are a sure sign that further investigation of the subject and experiments made with a view of determining the exact ratio of power between the magnets and armature will result in further improvement.

Another and very important consideration in the construction of dynamo-machines and electro-motors has not yet received that care and attention from scientific investigators which would lead to immediate progress. It is the mutual motion of the revolving armature with regard to its approaching to, or receding from the poles of the field-magnets. In nearly all the machines now constructed the pole faces of the cores of the field-magnets and those of the armature are of such a shape, and the latter is caused to revolve in such a manner, that only in a small portion of the revolution the poles either approach the poles of the field-magnets or recede from them. But the most successful production of reduced currents will be achieved, and the greatest amount of power will be derived from a motor, if attention is paid not merely to the *one* condition, that the armature should recede in the most highly concentrated magnetic field possible, but also that nearly the entire motion of the revolving armature should be either one of approach or of withdrawal. Let us first of all consider the case of a machine with two poles only of field-magnets and two poles of the revolving armature.

It is usual to give the active faces of the former such a shape that a section of the same represents a portion of a true circle. See Fig. 7.

In the ordinary machines now in use the radius of the circle described by the outline of the revolving armature, and that of the larger circle described in position by the section of the latter or active faces of the poles are nearly the same, and the two circles are concentric. (See Fig. 7.) The pole c of the armature only approaches the pole a of the field-magnets while moving from c to d, or where the intensity of the magnetic field of A is at its minimum. When continuing its motion from d to e and to f, the pole c can no longer be said to approach A, because the distance between the respective surfaces remains constant.

I therefore propose that the devices shown in Figs. 9 and 6 should be adopted. The radius of the circle, part of which is formed by the section d, e, c, is considerably larger than that of the circle described by the outline of the field of motion of the armature; d, e, c is, moreover, considerably less than the radius of a circle of the shape d, e, i, f, c, A, and that described by the outline of the field of motion of the armature are non-concentric. The pole p of the armature, when in its motion, approaches the pole, A, not only in its course from c to C, but also when in the most intense magnetic field of A, viz., whilst moving from C to e and d. Fig. 11 represents a section of the field-magnet's cores E F and G H, and pole's pieces N and S cast on two halves and mounted on a base board, to which they are fixed by the two bolts R and T. The same principles may be applied to machines with field-magnets of more than two poles (see Fig. 3); or the armature itself may be made of such a shape as to work under the conditions above stated (Fig. 4). But even if the poles of the armature and those of the field-magnets are of the ordinary shape, a machine with more magnets will be more perfect in its action than one with two poles only. Fig. 10 illustrates a machine in which the armature during nearly the whole of its motion either approaches to or recedes from

DOMESTIC MOTORS.

ALTHOUGH there is a large and increasing demand for small domestic motors, and several attempts have been made to supply it, the fact remains that there is no really satisfactory device which is at once cheap, efficient, and unobjectionable. It must be confessed that the conditions necessary for success are not easily met, but the prospective reward is sufficiently ample to encourage inventors to persevere until they succeed. The demand for motive-power in small workshops is also large, and in this case, how first-cost is the primary consideration, although economy in working is not lost sight of. The tendency of the modern system is to drive workers into large factories—to bring about a centralisation in manufacturing which checks the real advancement of the industrial classes, and certainly does not assist in the development of individual skill. With small and comparatively cheap domestic motors, a great deal of work would be done at home, and there would be a fair tendency towards overcrowding, which is indeed mainly by the desire to reside near the shop; but besides the array of real industrials, there are a host of amateurs who want a small motor to drive a lathe or a fret-saw, and to supply power generally to their *ateliers*. The choice of motive power appears to lie between gas, steam, or hot-air, for electricity is at present too costly, and water is not always available. For obvious reasons, steam-engines, as usually constructed, are objectionable, for they introduce an element of danger which it is as well to avoid, and even when well attended, are accompanied by dirt and heat, the smell of oil, and the escape of steam. An electric motor must be worked by the current produced by a machine, or by that obtained from a battery. In the one case a motor for the machine would be required, and in the other the use of acids and sundry chemicals would be regarded as a nuisance, even if the expense were a matter of little importance. Where water at a high pressure can be obtained, that would appear to offer the best means of supplying a motive power, with motive power, but besides the cost of the water, there is another objection that must be considered, and that is, the effect upon the total supply of a number of small engines running water practically to waste. In London, for instance, the companies do not care about supplying water for such purposes now, and would speedily set up a non-pressure if domestic turbines or hydraulic engines became fashionable. M. Fontaine, in a paper read recently before an association of civil engineers in Paris, gave some facts which show that the use of water in that city is practically out of the question, for though the pressure is equal to a head of 40 metres near the Seine, it is only 10 metres in the higher districts. The engines, of from 1 to 3d. per cubic metre, when not more than five cubic metres per day are used, though it is as low as 2½ when the daily consumption amounts to twenty cubic metres, a fact which would indicate that there is abundance of water at Paris. Taking the pressure as equal to a head of 20 metres, and allowing the motor an efficiency of 60 per cent., the quantity of water required for a work equal to six kilogrammetres per second will be 10 cubic metres in 10 hours, and the daily expense will therefore be about three shillings. It is some towns the charge for water is much less, and it is not impossible to obtain it in places with an efficiency of 80 per cent. Engines driven by springs are not properly motors, as they must be wound up themselves, either by another engine or by muscular power; but although they may be convenient in use they cannot possibly take the place of the domestic motor, although one enthusiastic inventor spent large sums of money in fitting spring motors to a tram-car. The efficiency of springs is very low, M. Fontaine putting it at 40 kilogrammetres for each kilogramme of metal in the spring, assuming it to be of the best steel. A weight raised by smooth ropes and easy-running pulleys gives a better return for the work stored up, but is not convenient, and would scarcely be adopted for any of the purposes we suggest. There is a possibility that some fortunate inventor will hit upon a means of using hot-air for a domestic motor without over-stepping the limits of size at which can be considered allowable. We illustrated on p. 369 of our last volume a "motion" of this kind, but we are afraid that, like other hot-air engines, it will be found too cumbrous for use in private houses. The hot-air engine has, however, the great advantages that it is easily managed, is fairly economical, and certainly free from danger: its durability will depend to a great extent upon the design, as will also its first cost. Looking at the matter from all points of view, it would seem that if a domestic motor is introduced it will take the form of a gas-engine, using either the gas supplied by the companies or that made from one of the cheap hydrocarbons. It possesses all the advantages of the other motors without their disadvantages, but if constructed on any of the present models, is rather costly. In comparing it with the steam-engine, however, it is probable that the first cost would not much exceed that of a small engine and boiler combined, while it would be unquestionably more economical in working. We should estimate that the saving alone in running expenses, as compared with a steam-engine, would about pay the interest on the extra cost, and as depreciation and cost of repairs would not exceed while similar items in the case of the steam-engine, we have, so far, a decided advantage in favour of the gas-engine. The latter, too, can be placed in almost any position, and is certainly as little trouble as any device—not even excepting the water-motor; while the hot-air engine at least requires attention in the matter of firing. The one disadvantage is the necessity for cooling the cylinder, but we are inclined to think that might be accomplished in a comparatively easy manner by means of a current of air charged with moisture around the cylinder, the external design of which would present a very large cooling surface. In the gas-engine we are imagining would be on the "silent" principle, as the noise made by the other forms would be intolerable in a house, and it should also be free from smell, or so arranged that the odours produced by working could be swept into a chimney or other air-shaft. Such an engine would be available for use in the kitchen, the "workshop," or even the drawing-room, and what with sewing machines, washing machines, knife-cleaners, and sundry other domestic appliances, not to speak of lathes, the demand would undoubtedly be very extensive, provided the resulting article supplied at a moderate price. If such a motor could be easily devised, we know very well that instead of suppressing its invention we should be writing a description of it; but something approaching the idea is already in the market, and it probably requires only a little stimulus, such as might be applied by the gas companies, to bring out a number of plans which might ultimately lead to the production of the domestic motor of the future. It is not impossible, however, that before a thoroughly successful domestic motor has been invented, some one will discover a means of transmitting power to a distance, just as water and gas are laid on to our houses, and that, in all probability, will take the form of electricity, generated by dynamo-machines driven by a fall or current of water. Sir William Armstrong, it will be remembered, has adopted this plan at his seat in Northumberland, and we believe some attempts of a similar kind are to be made in the United States, where there is an abundance of power, in many cases running to waste. In this country we have few falls, and not many streams, of water that could be utilised for the purpose, and we therefore think that the most promising line for experiment is in the direction of a cheaply-constructed gas-engine, which could be used with little trouble wherever a supply of coal-gas is available.

Electrician May 25 1888

2971. **Improvements in Dynamo-Electric and Magneto-Electric Machines.** A. J. Cloud. Dated September 20th, 1882.—(*Communicated from abroad by E. Reynier, of Paris.*—Not proceeded with.)

This invention relates to improvements in the original Siemens machine, which are shortly as follows—The fixed magnets are placed at right angles or perpendicular to the plane of revolution of the coil, as is the case with it. The ends of the core of the coil are connected by thin cores of iron, and a thin iron ring may be placed on the poles of the fixed magnet or magnets. The coils may be wound on the ordinary Siemens or Gramme shuttle, and are composed of flexible segments fixed on a disc of wood or other insulator, and insulated

from one another, but close together. The figure shows the machine with two metal rings as described above.

FITZGERALD'S MAGNETO AND DYNAMO-ELECTRIC MACHINES.

The improvements in magneto and dynamo-electric machines we now illustrate deserve the most careful attention, inasmuch as they show a decided advance in the right direction. The main idea of the inventor seems to have been to aim at perfecting the Gramme machine, and so, *first and foremost*, obviating the loss of the poles of a magnet and the ordinary system, he wholly or partially surrounds the armature longitudinally and transversely, thus increasing the effective inductive action. The ring is also magnetised directly and with the least possible loss, and the direction of the inducing magnetic polarity is such that it is constituted by the ring itself, as it should be. Fig. 1 shows a transverse sectional elevation of a magneto-electric machine, Fig. 2 is an elevation partly in section looking on to the left hand side of Fig. 1 with the driving pulley removed. In Fig. 1 A is the soft iron ring carrying 50 (more or less) coils, B, of No. 16 soft iron wire, and C, C are the pole pieces which are connected to the cylinder D. The ring A with its coils, is mounted on a brass bush, F, attached by a key, E, to the shaft P, mounted on suitable bearings in the standards G G, and at one end carrying the driving pulley H. The ring A is shaped or wholly surrounded by a hollow cylindrical ring, I I F, of wrought iron, or other magnetic material, which is also largest at the top and bottom. The opposite portions of this hollow magnetic ring are so formed with coils of wire as to constitute two magnets having their flat poles opposed on the vertical plane transverse to the ring A. The reverse direction of the winding near the poles required to produce this effect is shown at Fig. 3. The coils are secured by means of a screw-nut and washer, and held in position by thin lugs, J, projecting from their cores between the coils. The lugs J are bolted to the cylinder lugs, K, cast on the frame L. The ring A has preferably a deep groove, *a*, cut in it, circumferentially as shown. The reflector, C, consists of a cylinder of wood or other non-conducting material rigidly attached to the boss E, and having let flush into its inner circumference a series of strips of conducting material, M, insulated, and in number equal to the coils on ring A. The extremities of the coils are brought to the outside of the collector, and connected so as to form a closed circuit, the points of connection between adjacent coils being severally brought into contact with the conducting pieces M as shown at *n n*. Fig. 1 shows clearly the collecting brushes, the current being taken off at the horizontal central line, or the line of greatest polarity. Fig. 4 also shows a front view of the collector C. The brushes are flat springs of copper, O', each having at one end a contact piece, O, and being attached at the other end to a round bar, P, passing through a terminal, Q, and being fixed in position by a set screw, R. The terminal Q is fastened to the end of the bar P, having an adjusting-nut, S, tapped through it, and bearing on the plate under-neath. The set screw enables any required tension to be put on to the springs O', thus regulating the contact between O and the collector C. A binding screw is attached to the terminal Q, connected by screwcap, U, to the end of the machine. The whole of the current-collecting portion of the machine is liberated by means of this screw.

Considerable modifications are made in the construction of the ring. The method of construction is shown by Fig. 5. Ordinarily, in winding a number of coils of wire upon a ring, more or less of wire be lost, the same in each layer, inductive action is left between the coils. These interspaces are filled by Mr. Fitzgerald with soft iron ridge-shaped blocks, Y. These blocks can either be made with the ridge or segment and slipped on, the ring being made in halves for convenience in winding.

Fig. 6 shows a modified form of the ring A and the encircling magnets I F I. The ring being cylindrical instead of circular, and the encircling magnets having parallel instead of circular sides. The principle is the same whichever form is used. Fig. 7 is, however, illustrates a modification in which the ring A is wholly encircled on its cross section by coils, W, of wire in lieu of the coils on the ring. The encircling coils W are supported in a suitable framing, X, and the ring A, to rotate in the middle, is mounted between the coils W. Fig. 7, by one of which (preferably the upper) it is driven by friction. Therefore, the edge of this coil or pulley being of India rubber, as seen at 1 1, Fig. 8. The extremities of the coils of ring A are carried to a commutator, which is also described to a series of strips of conducting metal, Z, let flush into an insulating cylinder, Y, or of one or more coils, A', fitted round the outside of ring A. The current is taken off at segments of the outer circumference of the coils or let left in each between these longitudinal grooves, W, on these inner surfaces, where they pass over the ring A1 on the outside of ring A. The ends of the two surfaces of the ring and encircling collecting brought into very close contact. Fig. 9 is a transverse section taken at *a b*, Fig. 8 in a sectional plan of ring A at commutator, and Fig. 10 a section of Fig. 9, taken at line *c d*, Fig. 9.

It is obvious that in the three forms of machines shown per, namely, the ring A, and those on the inducing electro-magnets I F I or the inducing coils W, may be connected in multiple arc or in series, as is well understood. The apparatus may be advantageously constructed so that the current taken from either the ring A being employed to magnetise both of the inducing electro-magnets I F I or the inducing coils W, and the current for the external circuit of the circuit being taken from the second in ring A. The coiled ring A may be enclosed in a casing of soft iron, provided with a non-interrupted slot to allow of the passage of the wires from the coils. The arrangement of the inducing magnets I F I and the coils W is applicable to ring armatures generally. The saddle-shaped armatures they are called by Mr. Fitzgerald—of double or single circumference, are applicable to a great variety of machines, and may be used for the purposes of, for dynamo or magneto-electric machines the combination with a ring or cylinder-shaped armature of permanent or electro-magnets of double curvature, such as will encircle the ring-armature both transversely and longitudinally. (2.) And of the machines the combination with a ring or cylinder-shaped armature of electro or permanently magnetic ring constituting two magnets having their similar poles in a plane transverse to the armature axis. (3.) In similar machines the combination with a revolving coiled ring or cylinder of armature inducing coils completely encircling the revolving coiled ring or cylinder. (4.) The method of connecting dynamo and magneto-electric machines as described. (5.) The construction for use in dynamo or electro-magnetic machines or in other electrical apparatus of magnets illustrated in Figs. 1 to 6 of the accompanying drawings, the essential characteristic of such magnets thereof saddle-back magnets being that they are always curved in the direction transverse to the axis of the magnet or the line joining the poles), whilst they are sometimes curved also in the direction of this axis, and in the case of electro-magnets are surrounded with coils of wire every turn of which is partly convex and partly concave.

The Possibilities of the Electric Railway.

The highly interesting practical experiments of Dr. Werner Siemens, of Berlin, and of Mr. Edison, in connection with operating a railway with electrical motors, have attracted universal attention by reason of the novelty of the idea in the present generation, and of the apparent success of the experiments; and much speculation has been indulged in as to the possible

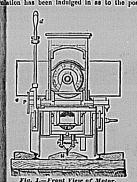

FIG. 1.—Front View of Motor.

future utility of this latest application of electricity. From the results that have been reached in the preliminary experiments of both the inventors above named, we risk very little in advancing the opinion that the practical success of the new method of propulsion has been demonstrated both from a technical and economical standpoint, and we may reasonably expect that the system extensively introduced in the near future for general purposes, and for the transmission of power for agricultural purposes, and in our cities for the delivery of parcels, the transfer of passengers and goods. For all these purposes a novel, quiet, and doubtless safer motive power than that do not see that the instant occur to us, the advantages of electricity as a motive power over steam and horses is too prominent to admit of question, and the economical method of propulsion by electricity, which we think may safely be assumed, the general introduction of the electric method of propulsion for the hauling of ores and minerals, plowing and other agricultural work, and cities for the transfer of passengers and goods for postal and freight service, is merely a question of time. We anticipate that the electric railway will very speedily into popularity on the strength of its introduction in a few prominent localities where its advantages over steam and horses in the absence of nuisance, freedom from liability to many forms of accident, and unavoidable, and from the annoyances of flying ashes, cinders, grease and other dangerous and offensive accompaniments of our present elevated steam railways, would strikingly demonstrate themselves. And while the anticipations of the advocates of the electric railway for our cities, as a substitute for the surface and elevated roads, and for the transaction of much of the

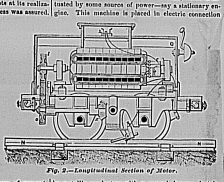

FIG. 2.—Longitudinal Section of Motor.

package and freight traffic over thoroughfares now thronged with vehicles, be realized, the single advantage that would be gained in the improvement of the sanitary condition of our cities in ridding us of the vast bodies of filth with which our streets are daily littered, can hardly be overestimated.

The history of the electrical railway resembles that of the majority of important and revolutionary inventions, in that several abortive attempts at its realization were recorded before its actual success was assured. Nearly forty years ago, the idea occurred to Prof. Page, one of the pioneers of electrical invention, and some years later Mr. Silby and Dr. Colton essayed the problem. But these early experimenters lacked the means for the economical generation of electricity with which our inventors of to-day are provided, on which account they failed. The only source of electricity available at that time, was the galvanic battery, the inconvenience, uncertainty and costliness of which was an insuperable obstacle. The development of the dynamo-electric machine within the past few years, however, has removed this serious difficulty from the path of inventors, and has given them what before was lacking, namely, a comparatively cheap means of generating and maintaining powerful electrical currents by the direct conversion of mechanical energy (no matter how generated, whether by steam, wind or water-fall) into electricity. In this form we can send our power to great distances over metallic conductors with comparatively little loss, drive electric locomotives or electric engines located at distant points, to do the work of the steam engine in our factories and workshops, or furnish light to towns and cities. Upon the development of the dynamo-electric machine, the electric railway has been made a possibility of the near future, and unless the signs of the times are most deceptive, we look for the most extensive adoption of the system in the course of the next decade.

Dr. Werner Siemens, of Berlin, whom name we mentioned at the outset of this article, is entitled to the credit of having revived in practical shape the forgotten efforts of Page and others of the past generation, by constructing and operating an experimental electrical railway in the grounds attached to the Berlin Exhibition of 1879. As this ingenious invention promises at no distant day to have a historical interest, we present herewith illustrations and a description of its operation and plans, together with some practical suggestions of the inventor that have grown out of the same.

The electric railway requires, first, a dynamo-electric machine at the terminus of the road, which is situated by some source of power—say a stationary engine. This machine is placed in electric connection by metallic conductors with a second dynamo-electric machine, which, properly mounted on a vehicle, the wheels of which are set in motion by it, constitutes the electrical locomotive. Thus we have the first dynamo-electric machine set in motion by the steam-engine at the terminus, the electricity generated by it is conveyed by the rails, or by some special conductor, to the second dynamo-electric machine, which is sets in motion, and actuates the locomotive. These are the essential parts of the electric railway. The details of Dr. Siemens' system are as follows:

Fig. 1 represents a front view of the locomotive, and Fig. 2 a longitudinal section.

The motion of the electrical machine is communicated by suitable gearing to the wheels of the vehicle on which it is mounted, and these are placed on rails of the ordinary construction. The electricity from the driving electrical machine at the station is conveyed to the locomotive through a special insulated central rail (seen in Fig. 1), the current built taken from the locomotive rail by a metallic brush, and returned to the first machine through the ordinary uninsulated rails, thus completing the circuit.

FIG. 3.—SIEMENS' ELECTRIC RAILWAY AT THE BERLIN EXHIBITION.

The stationary machine, it should have been stated, has one of its poles connected with the track rails and the other with the insulated center rail. The current, therefore, comes through the insulated center rail, traverses the metallic brushes in contact with the center rail, passes through the wires of the locomotive and returns through the wheels and track rails.

Fig. 3 shows a perspective view of the locomotive, drawing three cars, each containing six passengers. The current is thrown on or off by the driver, who sits astride of the motor and controls its motion. The performance of the locomotive here described, and which

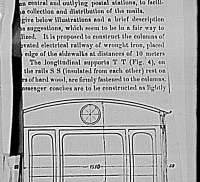

FIG. 4.—Siemens' Electrical Elevated Railway.

is capable of developing 2½ horse-power, attained a maximum of 14 miles per hour, carrying 18 passengers. Siemens' novel experiment attracted so much attention, that the suggestion was subsequently made to use the electrical elevated railway in the city of Berlin for the transfer of passengers, which, we are informed, has been received with favor by the municipal authorities. He also developed the idea of employing the system as a substitute for the pneumatic propulsion, in use in that and other European capitals, on central and outlying postal stations, to facilitate the collection and distribution of the mails. We give below illustrations and a brief description of these suggestions, which seem to be in a fair way to be realized. It is proposed to construct the columns of the elevated electrical railway of wrought iron, placed on the edge of the sidewalks at distances of 10 meters apart.

The longitudinal supports T T (Fig. 4), on the rails S S (insulated from each other) rest on the tops of the latter, and are firmly fastened to the columns. The passenger coaches are to be constructed as lightly as compatible with safety, and are designed to seat 15 persons. Each wheel is carried on an independent axle, and the axle bearers of each side are electrically connected. The two driving-wheels R R receive their motion from the dynamo-electric machine, which is placed under the bottom of the vehicle. The central rail in this plan is dispensed with, and the track itself forms the conductor, the plan being similar if not identical with that of Mr. Edison's, described in the June number of this journal.

Fig. 5 represents a special arrangement designed for the postal service, by the same inventor. The road is proposed to be carried on short iron columns S. On these rest, at suitable distances, to which are attached short metal pieces d' d', forming the side walls of an inclosed railway. Between these sheet metal strips, at suitable distances apart, are placed light wooden cross-ties, on which rest the light rails a' a'. Of these rails, one is placed at frequent intervals in electrical connection with the side sheets, which are covered above with a removable sheet-metal cover d, while the other is connected with all the iron columns. It is designed to run small four-wheeled wagons on this road by suitable electrical connections.

We are thus in a fair way to see this interesting branch of electrical invention specially developed.

à l'une de rotation et changent de polarité deux fois par tour.

Cette disposition rappelle jusqu'à un certain point la machine de M. Nimdet dans laquelle on aurait remplacé les aimants inducteurs par des électro-aimants.

L'idée neuve et personnelle de M. Cance consiste dans l'emploi de bobines spéciales, tant pour les inducteurs que pour l'induit, qui augmenteraient dans une grande proportion la puissance de la machine.

Chaque bobine se compose d'un noyau de fer formé lui-même d'une série de fils de fer très-recuits et très-doux, sur lequel on enroule deux couches de fil de cuivre isolé, puis d'une seconde enveloppe de fils de fer de mêmes dimensions placés suivant les génératrices du cylindre et maintenus par une nouvelle double couche de fil de cuivre enroulé, et

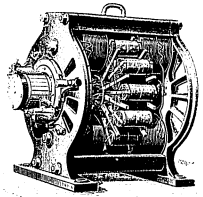

Fig. 1.

ainsi de suite, trois, quatre, cinq ou six fois suivant la puissance de la machine.

Cette disposition spéciale d'électro-aimant, qui date déjà de 1875 et que M. Cance a su si habilement appliquer à sa machine, présente plusieurs avantages.

Au point de vue des inducteurs, les spires traversées par le courant étant toujours très-rapprochées des tiges de fer qu'elles doivent magnétiser, leur action est ainsi énergique que possible; il en résulte donc que ces inducteurs constituent un champ magnétique puissant.

Au point de vue des bobines induites, ces petites tiges de fer très-recuites s'aimantent et se désaimantent avec la plus grande facilité, et comme elles sont ainsi très-rapprochées des spires à induire, et que, d'autre part, elles sont induites par leurs deux extrémités à la fois, on trouve là réunies toutes les conditions nécessaires pour donner aux courants une grande intensité, c'est-à-dire un champ magnétique puissant, des aimantations rapides et faciles, et une action inductrice produite à très-courte distance.

Pour ne pas donner trop de développement à la couronne formée par les induits, et par suite diminuer l'action de la force centrifuge, M. Cance a disposé les bobines en deux séries concentriques portant douze bobines chacune.

Dans ces conditions, la couronne extérieure, ayant une vitesse plus grande que la couronne intérieure, les actions d'induction devraient y être plus énergiques. M. Cance a paré à cet inconvénient en augmentant la surface du champ magnétique des bobines de la couronne intérieure. Par cette disposition, les courants induits sont sensiblement égaux dans les deux séries de bobines, car on compense par l'intensité du champ magnetique ce que l'on perdrait à cause de la diminution de vitesse.

Signalons encore une disposition de balais qui permet de changer instantanément leur calage suivant la vitesse, et de faire disparaître à peu près complétement les étincelles d'extra-

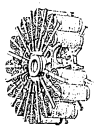

Fig. 2.

courant; le collecteur est placé à l'extérieur du bâti, il se trouve donc indépendant de tous les autres organes et peut être ainsi facilement nettoyé, démonté ou remplacé. Le même système permet de construire très-facilement des machines à courants alternatifs qui produiront des effets puissants sous un très-petit volume : c'est d'ailleurs le projet de l'inventeur.

Dans une expérience à laquelle nous avons assisté, la machine tournant à 1 100 tours a fourni un courant de 21 webers, mesurés à l'électro-dynamomètre de Siemens et Halske, à travers une résistance formée de 200 mètres de câble et un régulateur Serrin donnant un arc de 3 millimètres de longueur avec des charbons carrés de 9 millimètres de côté.

Ces chiffres représentent, à très-peu près, les résultats fournis par une machine Gramme, type d'atelier, tournant à la même vitesse.

La machine de M. Cance n'occupe pas un volume plus grand, elle emploie la même quantité de cuivre et a un poids total un peu moindre; l'enroulement des bobines, leur fixation sur l'arbre et leur remplacement s'effectuent avec la

plus grande facilité ; elle peut donc recevoir, au même titre que la machine Gramme, toutes les applications à l'éclairage, la force motrice, etc., si son inventeur veut la livrer dans des conditions satisfaisantes de bon marché, le seul facteur qui ait une influence décisive sur le développement des applications de l'électricité.

E. H.

NOUVEAU TÉLÉGRAPHE

ACOUSTIQUE, DE M. WILDE

Je ne sais trop si c'est M. Wilde lui-même qui a choisi le nom sous lequel on désigne sa nouvelle invention ; ce nom n'est pas clair, le système n'a rien de très-acoustique, si ce n'est que les dépêches ne sont pas inscrites par le récepteur,

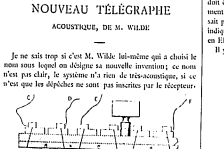

Fig. 1.

elles sont recueillies en écoutant le bruit que produit l'appareil, cela n'a rien de nouveau, tous les récepteurs actuellement en usage font assez de bruit pour qu'on puisse lire au son, comme disent les télégraphistes ; cela se fait constamment, et les Américains n'épèrent pas autrement ; leurs récepteurs sont tous des parleurs (*Sounders*).

Le système que M. Wilde vient de combiner et dont le premier spécimen a été présenté à quelques personnes, jeudi 16 septembre, dans les ateliers de la Compagnie parisienne (*l'Alliance*), est remarquable par d'autres côtés et constitue au contraire une combinaison très-nouvelle.

Le générateur d'électricité est une machine à courants alternatifs, les expériences ont été faites jeudi avec la machine de *l'Alliance*. Ceci est déjà un point nouveau ; on a, il est vrai, employé des machines à la télégraphie, et on a décrit dans ce journal (n° du 1er mars, p. 92) les procédés mis en usage pour cela en Amérique ; mais naturellement ce sont des machines à courants redressés, puisqu'on les employait simplement au lieu et place des piles.

Les courants alternatifs produits par la machine sont envoyés dans un circuit local qui forme le circuit primaire d'une série de bobines d'induction. Cette disposition est figurée dans le diagramme ci-contre figure 1. AB est le circuit en question, on voit qu'il est commun aux trois bobines M, N et P, comme à toutes les autres qui peuvent être installées. M. Wilde estime que, sur une machine ordinaire donnant six chevaux vapeur, on en pourrait placer trois ou quatre cents.

Les circuits secondaires de ces bobines sont au contraire indépendants comme cela est figuré en CD. C'est par eux que doit être fait le service télégraphique ; chacun peut généralement suffire à une ligne ; si cependant une bobine ne fournissait pas assez, on en couplerait deux ou plus, comme cela est indiqué pour les bobines N et P qui forment un seul circuit en EF.

Il y a là un mode de distribution curieux ; avec une seule

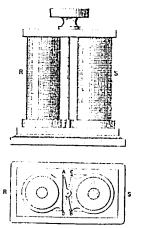

Fig. 2.

machine faire le service de plusieurs lignes séparément est un résultat qui pourra être utilisé.

Dans la construction des bobines, je signale un détail. M. Wilde les place par groupes entre deux culasses de fer doux qui rendent tous les noyaux solidaires ; cette disposition avait déjà été indiquée, mais les expériences de M. Wilde l'ont conduit à la considérer comme très-avantageuse pour la régularité de l'induction.

L'appareil que je viens de décrire sommairement met à notre disposition une série très-rapide de courants inverses ; il suffira d'interposer dans la ligne une clef Morse pour manipuler avec ces courants comme avec des continus ; la succession en est tellement rapide, qu'on ne peut frapper sur la clef le coup le plus sec sans en laisser passer plusieurs.

Il reste à voir par quel moyen on peut, au poste de réception, utiliser ces courants inverses, les appareils ordinaires n'étant pas disposés pour cela.

On the 6th of August, 1878, lightning struck the powder magazine at the Victoria Colliery, Barnsley, Yorkshire. At the time of the explosion the magazine contained about 7,000 lbs. of gunpowder. The magazine was an oblong building of brick, 9 feet long, 6 feet wide, and 6 feet high (internal dimensions), and it had a uniform thickness of three bricks. At the end was a heavy iron door, and at the other a lightning conductor, consisting of a copper wire rope seven-sixteenths of an inch in diameter. The point of the terminal rod was about 12 feet above the top of the building, and a similar length was carried into the ground, and terminated in rivery soil at a depth of three feet. The conductor was also carried a little distance along the roof at each end of the building opposite to that in which the iron door was placed. It was not observed with the iron door in any way damaged. On testing the conductivity of the copper rope it was found to be only 57·2 instead of 93 or 94 per cent. This deficiency should not have been overlooked, although the rope, when carried along the roof, down the iron door-post, and into the ground.

In January, 1879, lightning struck one of the pinnacles of the tower of Chester Cathedral, although on another pinnacle only 40 feet from it, there was a good copper conductor having a diameter of ⅜ of an inch weight. On testing the conductor by means of a galvanometer I found it and the earth connection in thorough order. In this case a point should have been placed on each of the pinnacles and joined to the main conductor.

In May, 1879, the steeple of the Church at Loughton, co. Ex-Northumberland, was struck by lightning, and damaged. The spire, 135 feet in height, had attached to it a thin rod of iron, 0·2 of an inch diameter, about 3 of an inch in external diameter, and 1 internal ; the copper being ⅛ of an inch in thickness. It was made in short lengths joined together by screws at the coupling-piece, but there was no metallic contact existing between the pieces, which were much corroded. The conductor was not in contact with the building, but was kept at a distance of 2½ inches by 21 insulators. The earth-contact was obtained by bending the tube and burying it in the ground at a depth of from 6 to 18 inches, the soil being dry loose rubbish, the earth terminal being only 3 feet. It was placed in a corner formed by a double-stem buttress, which came between the conductor and a lead-covered roof attached to the spire ; the distance between the conductor and the lead roofing being about 18 inches. The lightning appears to have come down the conductor a certain distance, and finding the road to earth bad, it passed through the buttress, dividing about two cartloads of stone, and then down the iron hinges, leaving from the lead-covered roof, and so to earth.

From the instances quoted, it is evident that it is not sufficient merely that rods of copper should be attached to a building, but it is necessary that once put up they should be regularly inspected to see if they are in good order, so as to be really efficacious. That this is rarely done is one of the main reasons why accidents by lightning occur in places nominally protected by conductors. It is, perhaps, not too much to assert that at present not one in a thousand of our public buildings in England are regularly tested.

There can be no manner of doubt that in the matter of lightning conductors they manage things better on the other side of the Channel than with us. The French Government are in the constant habit of consulting the most eminent scientific men on the subject of protecting public buildings against the destructive influence of lightning. There is scarcely an instance in which a British Government ever did such a thing. It is true the Houses of Parliament had lightning conductors erected upon them at a very great cost and under scientific advice. But all who understand the subject practically agree in saying that it is very doubtful whether the magisterial pile of buildings in which our legislators assemble is really, that is efficiently, protected. At all events, I understand the rods have never been tested since the conductors were erected in 1852. That the Victoria Tower should have been struck in June, 1858, and slightly damaged, tends to show that the conductors at that time were not in an efficient state.

From the examination I have made I am pretty correct in stating that one half of our cathedrals and three-fourths of our churches have not even nominal protection. For all that science has done, the Queen might any day be killed in her apartments at Windsor Castle, the Prince of Wales in Marlborough House, and the Prime Minister in Downing Street. To see the difference between England and France in this respect, one has but to cross the Channel between Dover and Calais. At Dover there are huge barrels of great length, on the top of high hills, exposed in the full fury of storms sweeping across the Channel, and the few conductors to be found upon them at long intervals are certainly not numerous enough for efficient protection against lightning, and their efficiency has never, so far as I can learn, been tested. The contrast in this respect on crossing the Channel is of the most striking. At Calais, the Hôtel de Ville, in the Grand Place, literally bristles with lightning conductors, and so do all the churches and chief buildings in the town. The same all over France, Germany, and Belgium. Without slavishly imitating our scientific neighbours, we might yet borrow some of the care they do upon the protection of our property as well as of our lives against the terrible effects of the electric force.

TROUVÉ'S ELECTRIC MOTOR

By M. TROUVÉ.

In the dynamic diagram of a Siemens armature is traced out, on making the armature turn a complete revolution between the magnetic poles which react upon it, it will be observed that the work is almost nil during two periods forming a considerable portion of the revolution. These two periods correspond to the times during which the cylindrical poles of the armature, having reached the poles of the magnet, move in front of them. During these two portions of the revolution, which are each about 90°, the magnetic surfaces destined to react one on the other remain at the same distance, and the armature has no motive force given it.

I have suppressed these periods of indifference and increased the useful effect of the machine, by modifying the shape of the bobbin ; the polar faces, instead of being portions of a cylinder of which the axis coincides with that of the system, are of a small form, so that on turning they gradually approach their surfaces towards those of the magnet, up to the moment when the hinder edge leaves the pole of the magnet. The action of repulsion then commences, so that the dead point is practically got rid of.

Fig. 1 shows a general perspective view of a motor constructed on these principles ; fig. 2 is a vertical section of the same, with a horizontal projection.

Fig. 1 is drawn to half size. A A C C is a fixed

ON THE BEST FORM OF MAGNET FOR MAGNETO MACHINES.

By W. LADD.

(Read before the British Association, August, 1880.)

At the British Association Meeting at Dundee, in 1867, I made some remarks upon different forms of magnets, and exhibited diagrams, showing by

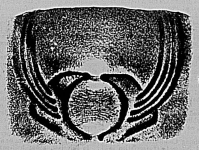

Fig. 2.

the lines of force—naturally arranged—the great superiority of the circular magnet where an armature is to be employed.

Since that time, some thousands of that form of magnet have been made for medical, mining, and other purposes.

Some months ago, in conversation with M. Breguet, of Paris, I showed him these same diagrams, and he was very much impressed with their importance; he has since then constructed a machine using the Gramme armature, and with a smaller quantity of steel in the magnets he has made a far more powerful machine than hitherto constructed with either the Jamin or the ordinary horse-shoe form. It is also more symmetrical in appearance and occupies less space.

With this machine I can heat to incandescence 10 inches of platinum wire by four turns of the handle, while to heat 11 inches of the same size

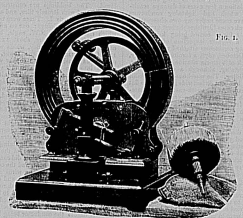

Fig. 1.

wire by a machine having a Jamin magnet, it took ten turns of the handle.

[This machine is shown by fig. 1. Fig. 3 shows the distribution of the magnetism about the field in which the armature revolves.]

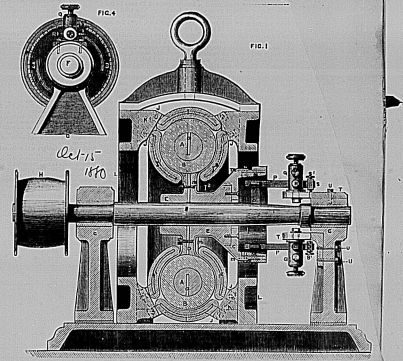
FITZGERALD'S MAGNETO AND DYNAMO-ELECTRIC MACHINES.

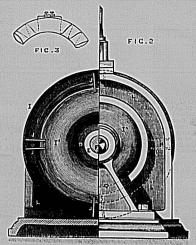
THE improvements in magneto and dynamo-electric machines we now illustrate are the invention of Mr. Desmond G. Fitzgerald, and deserve careful attention, inasmuch as they show a decided advance in one right direction. The main idea of the inventor seems to have been to aim at perfecting the Gramme machine; and so, instead of rotating the ring between the poles of a magnet on the ordinary system, he wisely or partially surrounds the ring with the magnet, and rotates the coils on the periphery of the inducing magnet. The ring is thus magnetised directly; and with the least possible loss, and the direction of the inducing magnetic polarity in the circle constituted by the ring itself, as it should be. Fig. 1 shows a transverse sectional elevation of a dynamo-electric machine; Fig. 2 is an elevation partly in section of the ring, to which the side of the coils with the end-plate and pulley removed. In Fig. 1 A is the soft iron ring carrying more or less, coils B of wire, all wound in one direction. The ends of these wires are connected to the collector C. The ring A, with its coils, is mounted on a hollow shaft D, driven by a bevel E on the shaft F, mounted in suitable bearings on the standards G G, and at one end carrying the driving pulley H. The ring A is almost wholly surrounded by a hollow electro-magnet I I, which, for convenience of manufacture, the ring I I² I³ I⁴ is divided transversely, of which the two represented by I I and I² are annular, while two are semi-annular, and make up the largest diameter I, the division between the halves being preferably at the top and bottom. The annular portions of the hollow magnetic ring are wound with coils of wire or bar constituting two magnets having their like poles opposed on the vertical plane transverse to the ring A. The reverse direction of the winding of the poles required is represented as it is shown at Fig. 3. The vertical sections of the electro-magnetic ring are united and held in position by thin lugs J projecting from their cores between the coils of wire. These lugs J are bolted to the magnetic ring by bolts K, cast on the ring I, and passing through a deep recess i cut in it circumferentially, as shown. The collector C consists of a cylinder of wood or other non-conducting material, rigidly attached to the boss E, and carrying on its outer surface the inner circumferences a series of strips of conducting material, 7 in the present instance, and in number equal to the coils on ring A. The extremities of the coils are brought to the outside of the collector, and connected, as by form a closed circuit, to the ends of connection between adjacent coils being severally brought into contact with the conducting pieces M as shown at n n. Fig. 4 shows clearly the collecting brushes, the contact being taken off at the ends of a diameter at right angles to the line of greatest regularity. Fig. 4 also shows a front view of the collector C. The brushes are flat springs of copper O, each having at one end a platinum point O¹, and being attached at the other end to a round the pillar P, passing through a key-plate Q, and being fixed in position by a set screw R. A short lever S is attached to the end of the bar P, having an adjusting screw S¹ passing through it, and bearing on the plate underneath. This screw enables any desired tension to be given to the springs O¹, thus regulating the contact frictional. The pillar P is fixed to and insulated from a plate T, connected by screws U to the end standard of the machine. The whole of these current collecting parts are thus readily liberated by means of these screws.

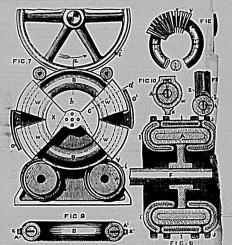
Considerable modifications are made in the construction of the ring. The method of construction is shown in fig. 5, which, similarly to fig. 1, shows a number of coils of wire upon a ring, more especially if it be of circular section and if the coils be composed of wire of the same gauge in each layer, interstices are left between the coils. These interstices are filled by Mr. Fitzgerald with wedge-shaped blocks V. These blocks may either be made with the ring, or separately and slipped on the ring being made in halves to receive them, as shown.

Fig. 6 shows a modified form of the ring A and the encircling magnet I I. Here the ring is made of a flattened band of circular section and the encircling magnets being ring-shaped to correspond. The principle is the same whichever form is adopted. In fig. 6 the interstices between the coils on the ring A, is wholly encircled on its cross section by coils W, in lieu of inducing magnets.

In figs. 7 to 10 illustrate a totally new form of machine in which the ring A is wholly encircled on its cross section by coils W, in lieu of inducing magnets. These encircling coils W are wound on to a suitable frame-work and are also wound







tinual contact, the surface of this roller or pulley being of india-rubber, as seen at i i, Fig. 8. The extremities of the coils of ring A are attached in a manner similar to that before described to a series of strips of conducting metal, Z, let flush into the surface of the roller or pulley, a double or single ring of metal round the outside of ring A. The coils are connected in succession to the outer circumference of the coils W left in such a manner as to form a set of wire. Preferably, the coils W are wound so as to leave a longitudinal groove W in their inner surface, where they pass over the ring A on the outside of ring A. The silvers of the two surfaces of the ring and encircling coils being brought into very close contact. Fig. 9 is a transverse section taken at a a, Fig. 9 shows a section of ring A at centre line, and Fig. 10 a section of coils W, taken at the line b b.

It is obvious that, in the three forms of machines shown permanent magnets may be substituted for the electro-magnets; the permanent magnets retaining substantially the same shape,

THE TELEGRAPHIC JOURNAL AND ELECTRICAL REVIEW.

Oct 15 1880.

VOL. VIII.—No. 185.

ELECTRIC MOTORS.

THE problem of the electrical transmission of power to a distance has given a considerable impetus to the invention of electric motors. The interchangeability of the electric generator and the electric motor is generally known to be possible; indeed, in almost all the experiments made on a large scale to show the possibility of the electric transmission of power, the motor and generator have been identical in construction. It seems to be admitted, however, that in several points the motor should differ from the generator, if the highest percentage of efficiency is to be obtained. In other words, the best generator does not necessarily form the best motor.

The tendency, in most cases, is to go back to the forms of motors which were designed plentifully many years ago. The motors of Trouvé, Wiesendanger, and others—the peculiar feature of which consists in the shaping of the armatures and inductors in such a way that the approach of the two together is gradual—were anticipated at least thirty years ago by the late Sir Charles Wheatstone, who invented and constructed several machines on the principle. These, we believe, may be seen in the museum of King's College, London, amongst the collection of that prolific inventor.

That there is a good field for invention in the direction of electric motors, can hardly admit of doubt, as their employment is likely to be considerable at no very distant date. At present the experiments made have been but fitful, though we believe that many are working quietly at the subject.

ELECTRO-MAGNETIC MACHINES.—A paper was recently read before the Academy of Sciences on the law of electro-magnetic machines, by M. Jaubert. With a given intensity of field, whatever the other conditions in which the machine works, from the moment when it gives maximum work the retardation is equal to one-eighth of the entire period; the intensity is constant and equal to the quotient by $\sqrt{2}$ of the absolute maximum of intensity; the electro-magnetic work is proportional to the velocity; and the velocity is in a constant ratio to the resistance.

CANCE'S DYNAMO-ELECTRIC MACHINE.

By E. HOSPITALIER.

Good dynamo-electric machines actually transform 80 to 90 per cent. of the power expended in driving them, into electricity. In the face of these figures

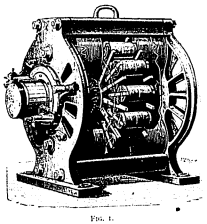

FIG. 1.

it is evident that there is but little improvement with regard to economic efficiency to be desired, but there is a good opening for improvements on the side of simplicity of construction and small first cost. It is with these objects that the machine of M. Cance has been constructed, and it appears to present certain advantages, which we will point out. The machine is composed essentially of two pairs of fixed inductors placed upon the frame, and of an inductor (represented by fig. 2) composed of 24 bobbins arranged in two series of twelve each, and connected to a Gramme commutator, seen to the left of fig. 1.

The bobbins cut the magnetic field parallel to the axis of rotation, and change their polarity twice each turn.

This arrangement is similar to a certain point with the machine of M. Niaudet (*Telegraphic Journal*, April 1st, 1876), in which the permanent inducing magnets are replaced by electro-magnets.

The novel idea of M. Cance consists in the employment of special bobbins and of special inductors, which augment in a great degree the power of the machine.

Each bobbin is composed of a bar of soft iron formed of a number of iron wires well annealed and very soft; on these are coiled two layers of insulated copper wire, and then a second wrapping of iron wires of the same dimensions as those forming the core, over these again are coiled two more layers of insulated copper wire, and so on, three, four, five, or six times, according to the power of the machine.

This arrangement of the electro-magnet, which dates from 1875, and which M. Cance has applied to his machine, presents several advantages.

As regards the inductors, the turns traversed by the current being always very near to the iron layers which they magnetise, their action is very energetic, and consequently these inductors constitute a powerful magnetic field.

As regards the induced bobbins, these little layers of well annealed iron, magnetise and demagnetise with great ease, and as they are thus very close to the inducing layers, and as, on the other hand, they are induced at their two ends at a time, they combine all the conditions necessary for giving to the induced currents a great intensity, that is to say, a powerful magnetic field, rapid and easy magnetisations, and an inductive action produced at a very short distance.

In order to avoid a too great development of the crown formed by the induced coils, and the consequent considerable action of centrifugal force, M. Cance has arranged the bobbins in two concentric series of twelve bobbins each.

Under these conditions, the outside crown having a greater velocity than the inside one, the inductive actions are more energetic in the former. M. Cance has got rid of this inconvenience by increasing the surface of the magnetic field of the inside bobbins. By this arrangement, the induced currents are velocity-equal in the two series of bobbins, for what is lost by low velocity is made up for by a more intense magnetic field.

We should point out an arrangement of the brushes which allows of the instantaneous change of their position according to the velocity, and which gets rid almost completely of the extra current sparks; the collector is placed outside the frame, it is thus independent of all the other pieces, and can be easily altered or replaced. The same system allows of the easy construction of machines with alternate currents which produce powerful effects within a very small space; this is another idea of the inventor.

In an experiment at which we assisted, the machine turning at the rate of 1,100 turns per minute, a current of 20 webers was give out, measured by a Siemens and Halske dynamometer, and through a resistance formed of 200 metres of cable and a Serrin regulator, giving an arc of 3 millimetres in length with minute carbons 9 millimetres thick.

These results represent, almost exactly, the results furnished by a Gramme machine, workshop type, turning with the same velocity.

The machine of M. Cance does not occupy a greater bulk, it employs the same quantity of copper and has a total weight a little less; the coiling of the bobbins, their fixing on the axle, and their replacement, is effected with the greatest ease; it can therefore be used in the place of the Gramme machine in all the applications of electricity, such as the electric light, the transmission of power, &c., if its inventor can bring it out at a low price, the sole factor which has any decisive influence in the development of the applications of electricity.—*La Lumière Électrique.*

2° *Mouvements longitudinaux.*

Les courants intermittents réguliers à périodes égales portent en outre produire des mouvements vibratoires longitudinaux dans les noyaux d'électro-aimants.

Le fait a été observé pour la première fois par M. Page en 1837, et étudié successivement par Delezenne, de la Rive, Beatson, Marrian et Gaugain.

De la Rive en a le premier donné l'explication par les mouvements moléculaires déterminés par l'aimantation. Le courant tend à disposer les molécules en files longitudinales, et celles-ci reviennent à leur position d'équilibre en vertu de leur élasticité.

D'après cette théorie confirmée d'ailleurs par l'expérience, les sons sont d'autant plus intenses que le fer est plus doux; les mouvements moléculaires y étant aussi d'autant plus faciles.

On comprend aussi pourquoi une tension exagérée qui diminue la mobilité des molécules, diminue l'intensité des sons, et pourquoi, lorsque le fil ou le noyau sont aimantés d'une manière continue, un courant intermittent y détermine des sons plus ou moins intenses suivant qu'il produit une diminution de sens contraire ou de même sens que l'aimantation préalable.

Les sons longitudinaux sont d'ailleurs accompagnés de sons transversaux dont les expériences de Wertheim ont donné l'explication.

Le téléphone de Reiss repose précisément sur ces faits.

C'est, en effet, un transmetteur de courants intermittents produits par une membrane animée d'un style métallique (analogue au phonautographe de Scott), qui produit les intermittences. Les courants intermittents arrivent dans un récepteur qui n'est autre qu'un fil de fer entouré d'une hélice tendue sur une caisse renforçante, et constituant ainsi une sorte d'électro-aimant particulier.

On fait ainsi reproduire au fil des sons longitudinaux identiques à ceux qui font vibrer la membrane du transmetteur.

On obtiendrait de cette manière aussi facilement des sons musicaux proprement dits, et même les sons complexes provenant de la parole articulée.

Le récepteur du téléphone de M. Ader, décrit dans ce journal (1880, p. 273), repose sur les mêmes principes, car sous l'influence des courants ondulatoires d'un transmetteur

VOL. VIII.—NO. 186.

A NEW ERA IN PUBLIC LIGHTING.

INVENTORS are still working hard to perfect or invent dynamo machines and electric lamps, indeed it seems that at the present time this branch of electrical science is receiving more attention than all the other portions combined.

It is doubtful if much improvement is possible on the well known machines already in the market, unless, indeed, some great discoveries should indicate an entirely fresh direction to thinkers in that field of investigation, but this seems hardly possible.

A good lamp, simple yet effective, durable yet economical to manufacture, is, we believe, still a desideratum; but both machines and lamps are for most practical purposes sufficiently good for the electric light to have made much more rapid advancement than it can be said yet to have done.

Why then is the development progressing so slowly? The reason, we think, is partly, perhaps largely, to be accounted for by the fact that hitherto most individuals or firms desiring to use the electric light have found that to obtain the necessary plant entailed too extensive an addition to capital expenditure. And this, particularly as the advantage of the light, in point of *general economy*, when used on such a scale as for warerooms, &c., is still held by some to be doubtful. If an instance were wanting to prove the pecuniary advantage when the electric arc is largely used, we might quote Mr. Swan's words in speaking before the Literary and Philosophical Society at Newcastle. That gentleman said that, at the Alexandra Palace two thousand gas lights, costing twenty-six shillings per hour, had been replaced by six electric lamps, costing only six shillings per hour.

What undoubtedly is now wanted is the central system for the supply of the electric current in large or small quantities; and this supply obtainable on analogous terms to those required for a supply of gas. If every one wishing to use gas were obliged to purchase the necessary plant for so doing, and superintend the working thereof, we think his ardour in that direction would be considerably damped, and most probably some other method of lighting ultimately adopted. It is with satisfaction then that we note that the central system is engaging the attention of two or three most influential firms on this side the Atlantic, and we also read that one of the companies in America interested in the Brush light is about projecting a similar system there. When once a success is scored the adoption of the electric light will progress with more and more marked rapidity. The public will be satisfied with the increased light or greater economy, and those who invest their capital in electric light shares, will, we believe, have no reason to be dissatisfied with their profits.

HEINRICHS' NEW RING ARMATURE AND THEORY OF THE GENERATION OF ELECTRIC CURRENT IN A RING ARMATURE.

A further improvement on the Pacinotti* ring armature has been made by Mr. Charles F. Heinrichs, the inventor of the electric lamps with circular carbon pencils.† As this improvement is of an important nature, and possesses very promising features, we shall fully describe its principle and advantages.

Mr. Heinrichs was led to devise the new form of armature through a close study of those of the existing forms, and by observing the manner in which the electric currents are generated in them; by this he formed a theory as to the action which the soft iron ring takes in the generation of electric currents in its surrounding insulated conducting-wire. Of this theory we shall make use in this article, with Mr. Heinrichs' permission. We shall have to refer to other already known ring armatures which are improvements on the Pacinotti ring, and we shall have also to draw comparison between those and the new one of Mr. Heinrichs, without which we could not well describe its merits and features. Several theories have been advanced, to explain the part which the soft iron ring plays in the generation of electric currents in the armature, but we have not yet seen an entirely satisfactory explanation of the action which the soft iron ring takes when in motion.

M. Antoine Breguet explains the action of the soft iron ring in his small pamphlet, "La Machine de Gramme," and part of his explanations are confirmed by Mr. Heinrichs' theory, as we shall see later on; but we think Mr. Heinrichs has gone a good deal further, and has not only endeavoured to discover the disadvantages of the existing armatures, but also constructed a form of the latter on which he overcomes those disadvantages in a satisfactory and simple manner.

It is well known that when a piece of soft iron is brought within the sphere of the coils close to a magnet (fig. 1) this piece of soft iron will become also a magnet, and the one end nearest to the magnet acquires south polarity and the other end north polarity. In the middle of the piece of soft iron a neutral line, *l l*, will be established, and if the piece of soft iron were surrounded with insulated conducting-wire, a current would be set up or generated in the entire length of the wire *in one direction*. As is well

Electricity from River Currents.

As inventor of this city proposes to utilize the swift current of rivers by systems of anchored floats carrying current wheels connected with electro-dynamic machines. The electricity thus generated might be conveyed to factories on the shores and set to work by means of electro-motors; or it might be used for lighting towns, or even for running trains on railways.—*Scientific American.*

17

courants induits qui se développent, non plus dans les bobines, puisque celles-ci sont en circuit ouvert, mais dans les aimants et même dans les noyaux de fer eux-mêmes, une partie des masses de fer, quelque précaution que l'on ait prise pour les diviser longitudinalement comme c'est d'usage.

On peut facilement reproduire cette expérience avec l'appareil suivant : une aiguille de boussole est suspendue, par un fil non-tors, entre deux masses de fer placées chacune en regard d'un des pôles de l'aiguille. Si alors on laisse le fil se détordre, on observe que la rotation de l'aiguille est plus ou moins rapide suivant que l'on met ou que l'on retire les masses de fer.

Le fait si remarquable de la production des aimants qui a été observé dans le fonctionnement de toutes les machines dynamo-électriques, tient évidemment à ces causes.

Aussi nous avons persuadons de recommander aux constructeurs de tes sortes de machines d'employer précédemment, malgré l'usage reçu du contraire, des masses de fer doux massives, et surtout d'isoler, et autant que possible de section circulaire, pour y faciliter le développement des courants induits, les aimants soient d'abord moins puissants que sous la forme lamée, mais le pense que, par le fait de la démonstration, ils les dépasseront promptement. Les noyaux de fer des bobines, en particulier, devraient se le composer, être traversés le plus possible, car les courants induits qui s'y développeraient, feraient écran à ceux de l'hélice.

L. PALLET.

FAITS DIVERS

Le journal la *Lumière électrique* en fait un plus grand cas. Il les suivra, pleins de bienveillance, les connaîtra souvent quelques lignes, vaut pour le savoir, non pour reproduire ses sentences, soit pour les soumettre quelques années. Voici ce qu'il dit de *Physical Review* au numéro de mai 1880 :

« Nous voyons avec plaisir que notre estimé confrère la *Lumière électrique* de Paris prend sa place parmi des publications les plus diverses consacrées exclusivement ou intimement supplément, c'est une revue mensuelle scientifique, et, comme notre confrère scientifique de Londres, *Lightning review*, *The Telegraphic Journal*, elle donne aux études de ses numéros des dimensions bien suffisantes. Elle s'est donnée le rétrait pour but d'encourager à ses lecteurs, dans des articles écrits avec lucidité, et par des gravures de grand prix, tous les perfectionnements et toutes les expériences qui se rattachent à notre science particulière — bien que particulier aussi ne soit pas trop d'abord — et comme nous de la télégraphie qui se rattache intimement à nos études, elle honore ses relations réciproques de la progrès de la science électrique. »

Progrès de l'éclairage électrique.

On vient d'inaugurer à Schaerbeek l'éclairage électrique du Jardin Royal Albert. Dans la première fois, dit le *Bruxelles*, que ce système reçoit d'éclairage a été appliqué sur une aussi vaste échelle. Depuis plusieurs mois d'essais ont lieu.

Trente lampes à foyer libre, placées dans l'intérieur du jardin, à une hauteur de soixante mètres au moins du sol.

Les vingt-six lampes sont disposées par petits groupes ou statuts de globes-verres, éclairages entre elles à des distances variant entre 125 et 200 mètres.

Chaque groupe se compose de huit machines Siemens, mues par une machine Siemens de la force de 30 chevaux.

La transmission du courant est effectuée au moyen par des fils recouverts aux poteaux télégraphiques, et, en partie, par des fils souterrains. La grosseur des fils en fer oblige cette même la distance qui sépare les lampes du foyer générateur. Ils sont figés, en effet, en cuivre qui est nécessité de laisser pour toutes les lampes. Les charbons sont aussi grands pour durer une heure. Cette fragmentation générale est combinée de façon que l'on puisse, au besoin, développer la puissance éclairé dans une proportion considérable. Les groupes de générateurs pourraient atteindre à demeure 2,000 et lampes, soit en tout 500.

Le jardin Royal Albert est actuellement éclairage avec deux à Schaerbeek un grand nombre d'amateurs et de curieux. Le spectacle était magnifique. Par un temps gaster humid, qui a fait remarcir la puissance de nouvel éclairage, une brume épaisse s'est formée pendant l'illumination, et on a pu juger par là des services que la lumière électrique est capable de rendre dans les mauvais temps. Rien que soumis par le brouillard les lampes n'en ont pas

CORRESPONDENCE.

TELEDYNAMICS.

TO THE EDITOR OF THE ELECTRICIAN.,,

SIR,—I have not by me Peclet's "Traitée on Heat" by which to verify Mr. Paget Higgs's figures relating to the number of calories which an iron wire might lose when heated to a temperature of 98 degs., and submitted to an atmosphere of 18°C. I believe, however, in the first place that these figures are considerably exaggerated, and in the next, that a telegraph wire of No. 8 B.W.G. could not be practically utilised for transporting motive power to a distance, by causing it to be traversed, as indicated by Mr. Paget Higgs, by a current of 200 webers.

In fact, a current of 200 webers, traversing a wire 1,000 feet long, with a resistance of 3 ohms, will represent, per second a total expended energy which may be expressed in kilogrammetres by the formula,

$$W = \frac{Q^2 R}{2 g 1} \text{ kilogrammetres per second.}$$

$$W = \frac{(200)^2 \times 3}{2 g 1} = 37402 \text{ kilogrammetres.}$$

That is to say, an energy in *horse-power* of $\frac{37402}{75}$ or 498·5 horse-power expended in the conductor in the form of heat in order to carry the motive power 200 metres (1,000 feet in distance). Thus, whilst the wire No. 8 B.W.G. might have been traversed by a current of 200 webers, *"with perfect safety and without appreciable heating effect,"* the loss which I indicate points out sufficiently that it would be of no interest to attempt practically such a mode of transmission.—Yours, &c.,

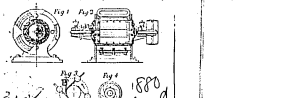
F. HOSPITALIER.

Nov. 14, 1880.

Journ. Tel. Oct. 16, 1880

LAW OF ELECTRO-MAGNETIC MACHINES.—Recent investigations by M. Joubert have shown that the retardation is equal to one-eighth of the entire period. The intensity is constant and equal to the quotient by 8/7 of the absolute maximum of intensity. The electro-magnetic work is proportional to the square of $\frac{7}{8}$. The $\frac{49}{64}$ is $\frac{3}{4}$ nearly, so the resistance $\frac{3}{4}$.

1880. Dynamo-Electric Machines: E. P. Alexander, London. (*Mech. Engineering, Architect, &c.*, 6 pp., 2 figs.) Relates to a dynamo-electric machine for producing currents of great power. For this purpose a cylindrical armature wound longitudinally is employed, and the field magnets are arranged in a star-shape electro-magnet, consisting of six bars (fig. 1) and over each one of the electro-magnets with coils of insulated wire, so as to form six poles. The armature (fig. 2) consists of a hollow cylinder, pierced with longitudinal holes, through which the wire is passed. The coils of the armature are wound in the form of rectangles lying their long sides parallel to the axis. The middle coil of each being such that the two sides are at the same time approaching and receding from the poles. The ends of the coils are connected to the commutator, in such a manner that the currents in each of the



Engineering

bars, are all in the same direction. The current is led to and from the armature by a wire wound round a cylinder of non-magnetic material. The ends are collected by brushes, which bear on the ends of the bars. In order to prevent the passage of induced currents from one bar to the other, through the iron of the armature, the latter is made in sections, these being insulated from each other by a paper wire which is extends from the iron in such a manner as to keep perpendicular against the commutator. The armature is made to revolve between the poles of the field magnets. The claim is made for the invention of a dynamo-electric machine having the new features. The patentee without further reference will show the disposition of the various parts. Drgs. 11, Desc.

autre exigence à satisfaire, surtout s'il s'agit de machines électriques.

Dans les machines électriques, où il y a de nouveaux progrès et de nouvelles dispositions réalisés tous les jours, l'expérimentateur se trouve assez souvent en présence d'un fait intéressant, de quelque chose qui, au premier coup d'œil, paraît être impossible. Alors la première question qu'il pose est toujours : N'y a-t-il pas de changements dans les instruments? Il est donc nécessaire qu'un possède des méthodes directes et simples pour vérifier les constantes de ces instruments.

Pour mesurer l'intensité du courant nous employons, dans l'établissement de Siemens et Halske, des électro-dynamomètres, dont la constante reste égale pendant des années; la vérification de cette constante n'est donc guère nécessaire. La détermination de cette constante se fait par le *poids de cuivre* déposé par le courant.

Mais, outre l'intensité du courant, il faut mesurer des tensions, comme j'ai montré dans l'article mentionné par M. Hospitalier; dans ce but nous avons construit un instrument qui indique directement les différences de tension.

Comme il y a un aimant dans cet instrument, la constante pourrait subir de légers changements, surtout si l'instrument ne se trouve pas très-loin des machines électriques; dans ce cas, on détermine la constante, il nous faut un moyen aussi simple que possible. Ce moyen consiste à relier l'instrument à une batterie de quelques éléments Daniell, lesquels avec précision; cette détermination se fait en quelques minutes.

Nachdem nun Siemens und ich auf eine solche Experiences, que si l'on procède de cette manière, la constante de l'instrument se détermine avec une exactitude de 1 pour 100, au moins, et que la force électromotrice de nos éléments Daniell est telle que le courant 1, $\frac{\text{Daniell}}{\text{U. Siemens}}$ donne 1,38 *gram. de cuivre* par heure. Comme c'est par cette *quantité de cuivre* déposée par le courant et par *l'unité Siemens* que notre « Daniell » est défini, il est facile de convertir toutes les intensités de courant en webers anglais.

De cette manière, quoique par principe nous adoptions le système des unités de la British Association, nous sommes forcé par les circonstances à employer d'autres unités en attendant le développement ultérieur du système.

C. Frolich.

Nous reconnaissons volontiers notre erreur au sujet des unités électriques, et nous sommes loin de la regretter, puisqu'elle nous a valu l'intéressante rectification qu'on vient de lire.

Cette erreur provient d'une mauvaise interprétation du texte allemand — assez confus d'ailleurs, — par notre traducteur, encore peu habitué à la terminologie scientifique.

Les conclusions de notre article du n° 14 n'en sont pas moins exactes pour cela et la confusion encore plus grande, M. Frolich reconnaît qu'il existe deux webers, un weber allemand et un weber anglais; nous prenons bonne note de cet aveu, notre article n'ayant pas eu d'autre but que de signaler cet inconvénient et de faire appel aux bons offices de la science pour le faire cesser.

M. Frolich donne pour la valeur de l'unité $\frac{\text{Daniell}}{\text{U. Siem.}}$ la valeur suivante :

$$1.\ \frac{\text{Daniell}}{\text{U. Siemens}} = 1{,}17 \text{ webers anglais.}$$

Si nous prenons la valeur de l'élément Daniell en volts et celle de l'unité Siemens en ohms, en adoptant les chiffres de M. Latimer-Clark (*Electrical tables et for*, nous trouvons que l'unité adoptée par M. Frolich a pour valeur.

$$1.\ \frac{\text{Daniell}}{\text{U. Siemens}} = \frac{1{,}079}{0{,}9176} = 1{,}113 \text{ webers anglais.}$$

Il y a donc *des centièmes* de différence entre la valeur donnée par M. Frolich et celle qui résulte des chiffres de M. Latimer-Clark.

En prenant pour la force électromotrice de l'élément Daniell la valeur donnée par sir W. Thomson (1,12 volts), on trouve 1,17 comme l'indique M. Frolich pour la valeur, en webers, de l'unité $\frac{\text{Daniell}}{\text{U. Siemens}}$.

En prenant le chiffre de M. Kohlrausch (*Annales de Poggendorf*, 1872) : Daniell = 1,138 volts, on arrive à 1,19 webers anglais.

Enfin, avec les chiffres du professeur G. C. Foster, (*Report*, page 113), 1 Daniell = 1,116, la valeur de l'unité $\frac{\text{Daniell}}{\text{U. Siemens}}$ = 1,212 webers.

L'unité adoptée est pratique par M. Frolich présente certainement de la simplicité, elle est d'une réalisation toujours facile, et les résultats sont *comparables entre eux*. Nous lui reprochons seulement d'être une unité arbitraire dont la liaison au système des unités absolues est assez mal définie, puisque la valeur de l'élément Daniell en volts varie, suivant les auteurs, entre 1,079 et 1,116, ce qui fait varier la valeur de l'unité d'intensité *pratique* entre 1,11 et 1,21 webers anglais.

Le chiffre de M. Frolich est une moyenne entre les valeurs extrêmes qui diffèrent entre elles de un *dixième* de leur valeur absolue.

Ces chiffres suffisent pour montrer combien nous avions *raison* de demander *de l'unité dans les unités*. ✱

E. Hospitalier.

LES MACHINES D'INDUCTION AMÉRICAINES

Il y a en Amérique, tout bien compté, une demi-douzaine de machines électro-dynamiques qui ont donné quelques résultats pratiques, mais deux systèmes seulement se disputent sérieusement le champ des applications à la lumière électrique; ce sont les machines Brush et Wallace-

de polarisation déterminés au sein des corps médiocrement conducteurs, et on verra combien les phénomènes ainsi produits sont curieux et variés. Ils pourront évidemment un jour contribuer puissamment à éclairer le usage obscur qui nous cache encore la nature de l'électricité.

Th. du Moncel.

(A suivre.)

DES LOCOMOTIVES ÉLECTRIQUES

2e article (voir le numéro du 15 octobre).

Les avantages du mode de traction électrique pour les tramways sur l'emploi des chevaux, sont les suivants :

1° Économie résultant de ce que les moteurs électriques atteignant facilement un rendement de 0,50 (qui est celui du travail maximum), il sera possible, en employant pour faire mouvoir les générateurs de courant, des machines économiques consommant moins de 1 kilogramme de charbon par cheval et par heure, de réduire la dépense de combustible à 9,50 par tonne brute et par kilomètre. En admettant qu'une voiture chargée pèse en moyenne 7 tonnes et fasse 100 kilomètres par jour, et que le prix du charbon soit de 35 francs par tonne, on voit que la dépense de charbon serait inférieure à 2 fr. 50 cent. par jour et par voiture, chiffre très-inférieur à celui de la nourriture des chevaux qui font le même travail. Il est à peine nécessaire de dire que je suppose le moteur électrique monté sur la voiture même, de façon à réduire le poids mort au minimum.

2° Le moteur électrique est incontestablement le plus simple de tous les moteurs connus. Il ne comporte aucun autre organe que les balais qui amènent le courant. On pourrait dire que c'est un arbre armé de la propriété de tourner quand on y lance un courant électrique. Par suite, il peut être confié au mancuvre le plus ignorant auquel il suffit d'indiquer le moyen de rompre ou de fermer le circuit.

3° Il présente tous les avantages des appareils à air comprimé, à cau chaude et à gaz d'éclairage comprimé, puisqu'il permet comme eux d'utiliser dans un locomoteur le travail développé par une machine fixe, tout en ayant sur eux une immense supériorité au point de vue du volume et de la simplicité de construction.

Ces brillantes qualités avaient, dans un avenir peu éloigné, le monopole de la traction des tramways au moteur électrique, lorsque la question de distribution du courant sera résolue, ce qui — je puis l'affirmer d'après mes recherches personnelles — ne saurait tarder beaucoup.

Application de la locomotive électrique au transport des lettres. Dans un article paru il y a quelque mois dans ce recueil, M. Hospitalier décrivait un projet de poste électrique de MM. Siemens. Or, au mois d'août de l'année dernière (1878), M. Dumpelmyer, ingénieur des lignes télégraphiques, avait conçu l'idée de substituer la traction électrique à l'emploi de l'air comprimé qui sert au transport des dépêches dans les tubes pneumatiques. Les motifs sur lesquels il s'appuyait pour proposer cette substitution découlent naturellement des recherches expérimentales qu'il a poursuivies pendant plus sieurs années sur le travail absorbé par l'exploitation des réseau de tubes pneumatiques de la ville de Paris. Il résulte de ces recherches, que, si de tous les modes de transport l'emploi des tubes pneumatiques est le plus commode, il est aussi de beaucoup le plus coûteux, sans que ce prix de revient excessif soit compensé par une rapidité exceptionnelle. La vitesse *moyenne* des petites véhicules circulant dans les tubes, n'est en effet que de 25 à 30 kilomètres à l'heure, à peine la vitesse des trains de marchandises sur les chemins de fer, et cependant l'effort exercé sur eux est égal à près de trois fois leur poids! Ce désastreux résultat est dû, comme l'a démontré M. Bontemps, à ce que presque toute la force motrice développée est employée à vaincre les frottements de la colonne d'air qui remplit les tubes, tandis que les frottements propres aux véhicules on *curseurs* qui portent les dépêches sont presque insignifiants. Cette résistance, développée par le mouvement d'une colonne d'air dans un tube, croît avec la longueur, et si cette dernière atteignait 15 à 20 kilomètres, par exemple, l'emploi de ce mode de propulsion deviendrait absolument impraticable, à moins qu'on n'employât une disposition ingénieuse dont l'idée est due aussi, je crois, à M. Bontemps et à laquelle il a donné le nom de *relais pneumatique*.

Ces considérations montrent que l'emploi d'une locomotive électrique à laquelle le courant serait fourni par une machine d'induction, présenterait pour ce genre d'application une supériorité très-considérable sur les tubes pneumatiques, même quand le rendement du moteur atteindrait à peine 0,20 à 0,25 du travail absorbé par la machine génératrice. Il faut remarquer, toutefois, que cette supériorité de la locomotive électrique consistait d'existence en détail mauvoir cette dernière dans un tube d'une section peu différente de la sienne propre, parce qu'elle aurait alors à refouler devant elle une colonne d'air qui, d'après les expériences citées plus haut, absorberait aussi très-considérable. Aussi, dans l'opinion de M. Bontemps, les petits chemins de fer destinés à la circulation des locomotives électriques devraient-ils être installés dans les galeries d'égout.

Supposons maintenant qu'une locomotive électrique pèse 15 kilogrammes avec ses dépêches, et qu'elle marche à la vitesse de 6 mètres par seconde sur une voie dont l'inclinaison ne dépasse pas 0,03, et que sur un réseau de 70 kilomètres de développement, tel que celui de Paris, on lance un véhicule toutes les cinq minutes : le nombre total de véhicules en mouvement, à un instant donné, sera de : $\frac{70000}{5 \times 60 \times 1} = 39$, ou environ 40. Le travail absorbé par chacun d'eux sera (en admettant que le coefficient de traction sur niveau égal à $\frac{1}{100}$,1 par seconde, *en remontant la rampe de 0,030*, et le travail total développé par les 40 véhicules sera de 216 km par seconde, soit moins de 3 chevaux. Il sera même certainement moindre,

19

Journal Telegraphique

The problem of the electrical transmission of power to a distance has given a considerable impetus to the invention of electric motors. The interchangeability of the electric generator and the electric motor is generally known to be important. Indeed, in almost all the experiments made on a large scale to utilize the principle of the electric transmission of power, the motor and generator have been identical in construction. It seems to be admitted, however, that in several points the motor should differ from the generator, if the highest percentage of efficiency is to be obtained. In other words, the best generator does not necessarily form the best motor.

The tendency in most cases is to go back to the form of motors which were designed scientifically many years ago. The motors of Trouve, Wiesenhanger and others—the peculiar feature of which consists in the shaping of the armatures and inductors in such a way that the approach of the two together is gradual—were anticipated at least thirty years ago by the late Sir Charles Wheatstone, who invented and constructed several machines on this principle. Those we believe may be seen in the museum of Kings College, London, amongst the collection of that prolific inventor.

That there is a good field for invention in the direction of electric motors can hardly admit of doubt, as their employment is likely to be considerable at no very distant date. At present the experimental models have been but fitful, though we believe that many are working quietly at the subject.—*The Telegraphic Journal.*

Engineering, Nov. 25, 1881.

ELECTRIC POWER.

The electric tramway which Dr. Werner Siemens has constructed in Berlin, between the suburb of Lichterfelde and the Lichterfelde station, is now regularly opened for passengers, and is giving great satisfaction. The rails are of the common railway pattern, but the gauge is only 3 ft. 3 in. A single car is propelled by the current at an average speed of nine miles an hour, though this rate can be doubled if necessary. A similar line has been erected at the Crystal Palace, Sydenham, as an attraction for visitors, but it is probable that electric tramways will be practically introduced into this country before many years are past. Velocipedes are now so common that it is not surprising to find that electricity has been applied to their propulsion. M. Trouvé, the well known French electrician, recently drove an English tricycle through the streets of Paris by means of electricity. In a Plantè secondary battery and a pair of Dupuy electric motors. The tricycle with its companion apparatus weighed 4 cwt., and went at the speed of an ordinary cab; but with some modification of the apparatus, M. Trouvé hopes to attain a rate of 12 or 15 miles an hour. The new accumulator battery of M. Faure will also help his purpose, and we may anticipate that velocipedes driven by electric power will by and by prove useful to the invalided or weakly. In Paris, too, electricity has been applied to work an air compressor at the top balloon factory of M. M. Chanchard et Cie, behind the Hotel du Louvre. The spare steam power of the engines has been utilized by two Gramme machines, one of which generates the current and the other transfers it into mechanical work. The energy thus transmitted is about a horse-power per minute.—*Engineering.*

Electro-Dynamic Paradox.

M. GERARD-LESCUYER has discovered a novel phenomenon, by so doing the current produced by a dynamo-electric machine into a magneto-electric machine. As soon as the current is closed the magneto-electric machine begins to move; it tends to take a velocity proportioned to the intensity of the originating currents, but it soon moves more slowly, stops, and turns in the opposite direction, going through a similar series of changes and returning to the first direction. This regular alternation of movement continues as long as the originating current is in action. In trying the experiments a Siemens' dynamo-electric machine, with continuous currents was used as the generator. The receiver was a small Jaboulay Gramme machine, with an ordinary permanent magnet, constructed by M. Breguet.—*Comptes Rendus.*

ABSTRACTS OF PUBLISHED SPECIFICATIONS, 1880.

1383. "Dynamo or magneto-electric machines and electric motors." THOMAS ALVA EDISON. Dated April 5. 6d. Relates to the rotating armatures, the arrangement of the commutator brushes or contacts, and the shaft of the rotating armature and commutator, which are applicable to both dynamo or magneto-electric machines and to electric motors. Fourteen figures illustrated. The armature core is built up of rings slightly conical in form, each ring being insulated from each other. The brushes or springs are set at an angle of about 45° to the axis of the commutator. When a brush or contact current is required it is done at several points simultaneously, so that the spark at the rupture is spread over several points, and does not burn up the contacts.

SUR LES ÉLECTRO-AIMANTS

CONSIDÉRÉS COMME ORGANES DE TRANSFORMATION D'ÉNERGIE

Par M. [illegible]

III

TRANSFORMATION ÉLECTRIQUE, PAR L'INTERMÉDIAIRE DU CHAMP MAGNÉTIQUE, D'UNE FORCE MÉCANIQUE EN ÉNERGIE ÉLECTRIQUE.

L'emploi des électro-aimants pour produire cette transformation, est un des plus remarquables qui puissent être imaginés: elle est caractérisée par la présence d'un champ magnétique dans lequel se meuvent les organes de transformation.

Ce champ peut être produit de deux façons; par des aimants ou par des électro-aimants, d'où résultent deux catégories d'appareils et une division toute naturelle de ce nouveau chapitre de notre classification.

Quoi qu'il en soit, l'énergie électrique produite se manifeste toujours sous la forme à laquelle on donne le nom de

20

courants induits, dont la constitution intime est encore inconnue, mais qui présentent cet caractère général de n'exister que pendant un temps extrêmement court, avec une intensité rapidement variable, et de changer de sens suivant le sens de la variation du mouvement des organes de transformation de l'énergie mécanique employée.

Deux cas. — *Champ magnétique produit par des aimants permanents, fixes ou mobiles.*

[A]. — *Production de courants intermittents ou oblitérés.*

Les appareils qui servent à produire des courants interrompus ou continus par transformation de mouvements produits dans un champ magnétique d'aimants permanents sont tellement connus des lecteurs de ce journal, qu'il me suffira de signaler les plus remarquables.

En effet, c'est la catégorie d'instruments dans lesquels les machines de Pixii, de Saxton, de Clarke, de Nollet et de l'*Alliance*, les premières machines magnéto-électriques de Wilde, de Gramme, de Siemens proprement dites ou modifiées récemment par M. Deprez... etc.

On les appelle ordinairement machines *magnéto-électriques*, mais il est certain que le mot *électrique* est inutile, étant entendu que ces machines sont des appareils destinés à produire de l'électricité. Le mot *magnétique* caractérisera la nature de l'inducteur.

On sait que ces machines, qui ont toutes été décrites dans ce Journal, produisent en général des courants électriques intermittents de sens contraire ou *alternés*, mais qu'on peut *redresser* ou rendre *continus* à l'aide de commutateurs dont la forme est bien connue. La machine Gramme produit en réalité directement à l'aide de ses collecteurs de courant plusieurs courants continus.

[B]. — *Production de courants des oscillations électriques d'intensité périodiquement variable.*

Les appareils destinés à produire cette trans-formation ne sont pas moins connus que les précédents.

Ce sont, par exemple, les transmetteurs téléphoniques...pile Graham Bell, etc., dont les plaques vibrantes sont mises en vibration à l'aides de sons musicaux ou des ondes aériennes complexes qui caractérisent la parole humaine.

Il est bien entendu que je n'ai pas à les décrire ici.

Je me contente de faire remarquer le rapprochement des instruments de ce genre des machines précédentes. Effectivement, *au fond*, ils ne diffèrent les uns des autres que par le mode de mouvement des organes, vibratoire pour ces derniers, circulaire pour les autres.

Il en résulte que dans l'essai de classification rationnelle que je donnerai plus loin comme résumé de ce chapitre, les téléphones G. Bell, Gower,... doivent être rapprochés des machines qu'on nomme aujourd'hui magnéto-électriques.

DEUXIÈME CAS. — *Champ magnétique produit par des électro-aimants, fixes ou mobiles.*

Les appareils qui produisent la transformation d'énergie mécanique en électricité sous l'influence d'un *électro-aimant inducteur* sont représentés par les transmetteurs téléphoniques sans pile dont je viens de parler, par les machines très-importantes, et dont le nombre s'accroît tous les jours, de façon qu'un essai de classification, permettant de reconnaître dans ces variétés d'une même famille, ne paraît pas inutile.

On a donné à ces machines le nom de *dynamo-électriques*... Ce nom ne me paraît pas bien choisi, et, avant que l'usage ne s'en répande tout à fait, peut être vaudrait-il mieux le changer.

Le premier mérite d'un nom, en effet, lorsqu'il sert de base à une classification scientifique, n'est-il pas de représenter *exactement* la chose qu'il sert à nommer? Or le mot dynamo-électrique ne peut pas désigner clairement un appareil destiné à transformer l'énergie mécanique du mouvement en électricité; car le mot grec *dunamis* signifie *force* et non mouvement. Mieux vaut évidemment employer un mot dérivé de *kinema*, qui signifie mouvement, et d'un Ampère à dire *électrocinétique* et M. Thomson *électrique*, mots universellement employés aujourd'hui.

Je proposerais donc de substituer au nom de dynamo-électrique celui de *cinéto-électrique*, et d'appeler *transformateurs cinéto-électriques* tout instrument, appareil, ou machine, quels que soient ses organes mécaniques, susceptible de transformer de l'énergie mécanique en électricité.

Mais alors on a ainsi une dénomination très-générale qui s'applique à plusieurs groupes d'appareils ou de machines, on plutôt à plusieurs modes de transformation, et qui ne peut *caractériser* avec une précision suffisante des machines particulières comme celles dont nous parlons et qu'on nomme actuellement dynamo-électriques.

Effectivement, dans une classification complète, que je donnerai plus tard, je montrerai que les transformateurs *cinéto-électriques* forment 2 familles d'après la 1re ou la transformation *directe* et dont je n'ai pas à parler aujourd'hui, la 2e ou la transformation ne peut s'opérer que par l'intermédiaire d'une induction, d'un *champ d'induction*, qui peut d'ailleurs être produit : 1° par une masse d'électricité à l'état statique ou potentiel; 2° par un courant électrique constant ou continu; 3° par un aimant permanent (c'est le cas des machines dites actuellement magnéto-électriques); 4° par un électro-aimant (c'est le cas des machines dites actuellement dynamo-électriques).

De là 4 classes d'appareils caractérisés par la nature de l'inducteur ; mais je n'indiquerai dans le tableau ci-après que la classification relative aux deux dernières, les seules qui se rapportent au sujet général qui nous occupe en ce moment, c'est-à-dire l'utilisation des électro-aimants.

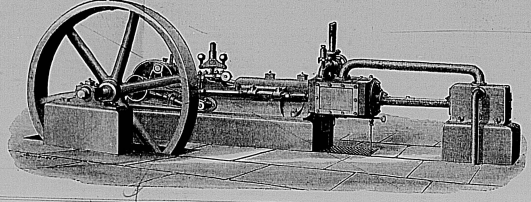
Dans cette manière de voir, une machine de Clarke serait une machine *cinéto-électrique* de 3e classe ou à *inducteur magnétique*, ou, en abrégeant, une machine *cinéto-électrique* : les nouvelles machines de Gramme à lumière seraient des machines *cinéto-électriques* de 4e classe ou *électro-magnétiques*. D'ailleurs, dans l'usage courant, on pourrait supprimer le mot cinéto-électrique et n'employer que les mots *magnétique* ou *électro-magnétique*.

Voici maintenant les bases de la classification dont le tableau synoptique est donné ci-après pour les transformateurs de 3e et de 4e classe.

HORIZONTAL CONDENSING ENGINE.

USED FOR DRIVING THE ELECTRIC LIGHTING MACHINERY AT THE ROYAL ALBERT DOCK.

BY MESSRS. MARSHALL, SONS AND CO.



passengers at 5.30 p.m. Steam of 150 lb. pressure and 150 revolutions per minute were steadily maintained all day, and, beyond the bearings requiring adjustment, the boat and machinery are, as we have said, none the worse for the four months' cruise. The directors of the Peninsula Company, preferring to leave the machinery in the exact condition in which it arrived in England, no attempt whatever was made to remove any of the evidences of wear and tear, thus giving those present the opportunity of judging for themselves of the practicability of working very highly pressure steam with economy. The *Andromache* is not only the smallest steamer that has ever steamed across the Atlantic, but is probably the only one of her size in England capable of performing such a feat. Her captain and crew are so satisfied with the working of the little vessel that they have expressed their willingness to take the *Andromache* either back again to America or to the most distant part of the world. When it is considered that the vessel is only 32 tons register, 70 tons gross, it must be admitted that she is a very extraordinary little craft, and has accomplished a remarkable feat in ocean steam navigation.

(To be continued from page 222.)

ENGINE FOR DRIVING ELECTRIC LIGHTING MACHINERY.

ON another page we have described the general arrangements for lighting the Royal Albert Dock by electricity, as carried out by Messrs. Siemens Bros. To drive the current-generating machinery there is in each of the four stations a horizontal condensing engine, with Cornish boiler, which were all supplied by Messrs. Marshall, Sons and Co., of Gainsborough. The accompanying engraving represents one of these four engines, which are all of the same type. They are of 30 horse-power nominal each, with 14-inch cylinders, and 24-inch stroke, running at 70 revolutions per minute. The flywheel is 14 feet in diameter, and the cylinders are steam-jacketed. Each engine is fitted with Messrs. Marshall's automatic expansion valve gear and jet condenser. The expansion gear consists of a sensitive and powerful governor, of novel construction, acting through a link and die on to an expansion cut-off valve working at the back of the main slide valve. The ordinary throttle valve is dispensed with, and the speed of the engine is controlled by means of the expansion valve, which regulates the admission of steam into the cylinder exactly in proportion to the duty performed by the engine. This gear is very simple and reliable in its action, automatically regulating the speed with very rapid fluctuations, and is adapted either for heavy or light work. The condensers are of improved construction, adapted for high speeds, the valves and seats are of brass, with Harbutt's india-rubber valves. The air-pump is connected direct to the tail end of the piston rods, and a distance piece is introduced between cylinder and condenser, ensuring speedy and accurate relative adjustment of these parts in erecting the engines. The arrangement of the foundations for the engines also reduces the work to the simplest character. The boilers are Cornish, multitubular type, each 15 feet 6 inches long, and 7 feet 8 inches in diameter, fitted with thirty-two tubes, each 4 inches in diameter. We need hardly say that the design and workmanship throughout are excellent, and that the engines

SPONTANEOUS COMBUSTION IN COAL CARGOES.

THREE weeks ago we considered it our duty to direct attention to some recent cases of spontaneous combustion in coal cargoes, and to offer a few remarks on the liability of coal cargoes in general, and Scotch coal cargoes in particular, to ignite without any apparent cause. We urged that greater precautions should be used in the shipment of these cargoes, in the interests not only of exporters and underwriters, but of our merchant service, whose lives are needlessly endangered. The subject having attracted considerable attention, and called forth the letter which appeared in our last issue from Professor Abel, one of the ablest and most active of the Royal Commissioners appointed in 1875 to inquire into the spontaneous combustion of coal in ships, we need not offer any apology for so soon returning to the subject, and for printing it in a more exhaustive manner. There is the less need for this, inasmuch as since our article appeared several fresh cases of spontaneous combustion have been reported, chiefly again in Scotch coal cargoes, thus adding force to our previous argument that the coal shipped north of the Tweed either contains so much more sulphur than other kinds, that it is more liable to generate combustion, or that less care is exercised than at the southern ports in its shipment.

In order to render clear our subsequent observations, we would in the first place remind our readers that five years ago, the present subject was attracting considerable attention, and a Royal Commission was moved for and appointed to inquire into the matter. The Commissioners consisted of the Right Hon. H. C. E. Childers (chairman); Sir George Elliot, Bart., Mr. H. H. Vivian, M.P.; Professor Abel, Dr. Percy, and Messrs. Richard Cory, George Duncan, John Fenwick, John Ferguson, Charles Healy, and Wm. Young. With the selection of these gentlemen we have no fault to find, but at the same time it will doubtless occur to those of our readers who are familiar with the subject, as it has occurred to us to say that the practical experience and knowledge, and the shrewd common sense of the popular member for the Cardigan Boroughs would have proved invaluable in the deliberations of the Commission. Be that as it may, the Commissioners duly met, patiently waded through a mass of written evidence, protests of captains, underwriters, and others to the communications or queries, reports, recommendations, and such-like; and carefully examined a large number of witnesses of greater or less experience. Copies of the papers, and of the evidence of the witnesses, along with the recommendations of the Commissioners, were published the following year, 1876, and although the evidence as reported contains a large proportion of what may be called table-talk,—several of the witnesses availing themselves of the opportunity to air coalfacts and even to cry up or damage the reputation of particular descriptions of coal,—there is no doubt the ponderous volume of 373 pages is well worth perusal, as it contains a vast amount of most useful and interesting information connected with the question under discussion.

The number of witnesses examined being over thirty, it would be impossible within the limits of an article to wholly separate the wheat from the chaff, or to review the evidence in full. We shall therefore content ourselves by directing attention to the evidence given by one of the most important witnesses, and then pass on to consider the Commissioners' report. Mr. Henry Johnson, McCulloch, consulting coal engineer to the Admiralty, stated that he had been connected with the coal trade for more than thirty years, and had had six or seven years' experience in shipping coal for the Government. In the course of his examination, after recommending a system sometimes practised in the north of England, and always at Cardiff at the commencement of the loading of each large vessel, namely, that of lowering coals into the holds of ships, to prevent unnecessary breakage; and also the use of smaller screens than was customary, with the same view, he said—

"The larger the coals the greater the value and the less danger there is from fire." He said he would not like to ship bituminous coal in the dry state, therefore more capable of excluding anything like air. The smaller coals are left between the pieces of coal, the better it is, and the more opportunity there is for the air to circulate round the coal. Of course it is the want of air, in my opinion, that causes the combustion."

He then gives evidence on the question of moisture, and its effect upon the coal:—

"Very often," he says, "I have seen coals put on board ship in a most slobbery way; that is to say, I have known the sides of the ship to be wet and damp, and sometimes I have known even water to be in the ship, quite apart from any moisture in the coals themselves; and my experience teaches me this, that if coals are even moist, much less damp, the bi-sulphide in the coals (because all coals have it, seeing perhaps the best part of South Wales, at the throttle coal) except that coal I know of no coal that is free from sulphur) becomes, through its oxidisation, turned into sulphide of iron by a natural process, and during that time, naturally, sufficient caloric is generated to cause combustion in the carbon of the coal."

Then with regard to ventilation, Mr. McCulloch said he did not think there were any ships that were ventilated, or, if there were, they were so badly ventilated that the ventilation was not worth speaking about. Lastly, as to the practice of double-screening, alongside ship, this witness says:—"I think it is obsolete." At least, I hope it is. It is obsolete as far as the Admiralty is concerned. I tried to stop that waste of coal (besides the cost of it, more per ton) very soon after I took office . . . It makes the coal worse and is expensive." Upon the foregoing we would remark that Mr. McCulloch's evidence appears to us to be of very great value, and worthy of the utmost attention, as does the question of coal being shipped as large and as free from moisture as possible, and the urgent necessity of having cutters properly ventilated." At the same time, we cannot but think his remark as to the "obsolete," or worthlessness, of ventilation in the vessels which came under his notice rather sweeping; for we know, and the appendix to the Commissioners' report proves, that many shipowners and masters have for a long time given this matter their most serious and anxious attention. Then, on the question of double screening, Mr. McCulloch, in our opinion, is mistaken, both in theory and fact, and it is hard to reconcile his remarks on that subject with his previous evidence as quoted by us. Moreover, we must express our extreme disappointment that this very important and well-known method of getting rid of the small coal did not receive from the Commissioners the attention it deserved. In fact, although they hovered round and round about it they appear to have practically

EDISON'S NEW DYNAMO-ELECTRIC MACHINE.

The remarkable activity prevailing at the Menlo Park laboratory and machine shop, and the evidences of the enormous outlay of capital which one sees at these works on every hand, are convincing proofs of the good faith and thorough earnestness of Mr. Edison and his co-laborers and supporters. The great work of perfecting a complete system of electric lighting in all its details is necessarily a very slow operation, for much more work may be urged, as time-tests of the endurance of lamps, perfection of the insulation of the underground conductors, and a hundred other time-consuming operations must, of necessity, be gone through with.

As it is Mr. Edison's determination that his system of electric illumination shall not be presented to the public until it is complete and commercially practicable to the smallest detail, he would be sorry, we can afford to wait patiently for the perfected thing, rather than be subjected to the trouble and possible disappointments attending the perfecting of the system while it is in public use, as is commonly the case with great inventions.

Besides carrying to a successful issue the grand experiment of illuminating a large out-of-door area with incandescent lamps, Mr. Edison has practically demonstrated that the highest economy in the conversion of power into electricity can be reached only by the use of very large machines, and by the direct application of the power to the armature without the intervention of belts or other means of transferring power.

Our engraving represents a gigantic dynamo electric machine approaching completion at Mr. Edison's machine shop, and designed to replace sixteen of the largest machines of this kind previously made. They name and the driving engine are both mounted on a massive cast-iron bed, 8½ by 7 feet and 2 feet deep, very heavy and strongly ribbed, the entire machine weighing 8 tons. Near the middle of the bed is mounted the dynamo electric machine, which, we believe, is the largest ever constructed. Its field magnets, three in number, are 6½ feet long. The armature is 2 feet 6 inches in diameter and 28 inches long, and weighs 1½ tons. The engine is 100 horse power, of the Porter-Allen type, built especially for this purpose at the Southwark Foundry, Philadelphia. Its stroke is 16 inches. The internal diameter of its cylinder is 9 inches. The crank disk is placed on the end of the armature shaft. Steam pressure, 120 lb. per square inch. The engine cuts off at one-fifth of the stroke and makes 600 revolutions per minute. The working pressure of the dynamo is 140 volts; the resistance of the armature is one two-hundredth of an ohm.

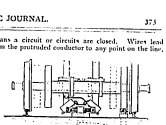

FIG. 2.

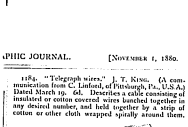
and are caused through suitable mechanism to make or break a circuit there also when required.

1156. "Magneto and dynamo-electric machines." J. H. JOHNSON. (A communication from A. de Mérites, of Paris.) Dated March 16, 48. Consists in enabling these machines to furnish an alternate current without the employment of an exciting machine. The inductors are magnetized by the alternate current itself without the necessity for changing its direction by means of a commutator or collector. Taking the machine known as De Méritens as an example, the coils of the ring are wound in such a manner that the exit wire from one coil is soldered to the exit wire of the next coil, and the extremity of the entering wire of one coil is soldered to the entering wire of the next coil. Hence it results that there are two entering or two exit wires leading to the binding screws where the current from the machine is collected. It also results that all the coils of the ring are traversed by one current, which changes its direction during each revolution as many times as there are coils in the ring. (*Provisional only.*)

1351. "Micro-telephonic apparatus." R. H. CUTLER-NEVAY. Dated March 17, 48. An iron or steel ribbon or core, with a soft iron on the base is, after being polished with a resisting medium, coiled with a number of lengths of wire insulated and connected by one end of each length to the bobbin. The bobbin is connected with a pendulum or spring of any suitable metals, either in the form of spiral or flat springs, coated with a resisting medium, the intention being to obtain delicate vibratory motion with the object of getting telephonic effects with less resistance as compared with carbon as generally used. (*Provisional only.*)

1478. "Dynamo-electric machine." JOHN PERRY. Dated March 28, 48. The object of this invention is to get a very intense magnetic field, and at the same time to have the currents generated to be continuous. In the machines of Gramme, Siemens, &c., the winding of the wire bobbins takes place, as nearly as possible, in the plane containing the axis of rotation. In the new invention each winding of wire on the rotating part of the machine makes a decided angle with the axis of rotation. Fig. 1 is the vertical elevation of the machine; *e f* is a shaft made to rotate; *a b* is a ring of phosphor bronze on which a great number of thin wedge-shaped coils (*c*, fig. 2) are packed so as to form an annular armature whose section is shown at *k*, fig. 3. The plane of each winding of this armature makes an angle of 30 degrees with the direction of motion when turning with the shaft. The armature is firmly fixed to the shaft, and is kept from changing its shape during rotation by means of the wooden discs, *i*, *i*, which embrace the coils on the inner parts of the ring, and which are bolted together and fastened to the shaft by the screws and collar shown in the figure, and by means of the outer rings of wood and metal, *l*, *l*, *l*, which are bolted together, embracing the outside of the

1189. "Telegraph wires." J. T. KING. (A communication from C. Linford, of Pittsburgh, Pa., U.S.A.) Dated March 19, 68. Describes a cable consisting of insulated or cotton covered wires bunched together in any desired number, and held together by a strip of cotton or other cloth wrapped spirally around them.



The interstices are filled with melted paraffin, coal tar, or similar material, or the wires are immersed in melted paraffin, coal tar, or similar material, as or before they are bunched. The cloth wrapper is then coated externally with coal tar, asphaltum, rubber, cement, or other elastic impervious material. Then, if desired, another strip of cloth may be wound on it spirally in the opposite direction, and coated in like manner. The fig. shows a container having a box or bed, which may be of cast iron or other suitable material, preferably protected by tarring or otherwise coating its exterior. Its interior is fluted or grooved, as indicated at *b*, to form receptacles for the wire, and whole interior surface is coated with porcelain enamel, as at *c*. Upon the bed is a cover, *d*, adapted to fit within the flanges, *e*, and rest upon the shoulders, *f*.

M. DE MERITENS has completed the construction of one of his magneto-electric engines intended for lighthouse illumination. An experimental trial took place on March 25 before MM. Becquerel, Cornu, Mascart, and other members of the Technical Commission of the International Exhibition. It was proved that with fifteen horse-power his machine illuminates at once more than thirty Jablochkoff lights, and that it could, at a moment's notice, be used in a regular way for marine purposes.

THE TELEGRAPHIC JOURNAL AND ELECTRICAL REVIEW.

VOL. VIII.—No. 186.

A NEW ERA IN PUBLIC LIGHTING.

INVENTORS are still working hard to perfect or invent dynamo machines and electric lamps, indeed it seems that at the present time this branch of electrical science is receiving more attention than all the other portions combined.

It is doubtful if much improvement is possible on the well-known machines already in the market, useless, indeed, some great discoveries should indicate an entirely fresh direction to thinkers in that field of investigation, but this seems hardly possible.

A good lamp, simple yet effective, durable yet economical to manufacture, is, we believe, still a desideratum; but both machines and lamps are for most practical purposes sufficiently good for the electric light to have made much more rapid advancement than it can be said yet to have done.

Why then is the development progressing so slowly? The reason, we think, is partly, perhaps largely, to be accounted for by the fact that hitherto most individuals or firms desiring to use the electric light have found that to obtain the necessary plant entailed too extensive an addition to capital expenditure. And this, particularly as the advantage of the light, in point of *general economy*, when used on such a scale as for warerooms, &c., is still held by some to be doubtful. If an instance were wanting to prove the pecuniary advantage when the electric are is largely used, we might quote Mr. Swan's words in speaking before the Literary and Philosophical Society at Newcastle. That gentleman said that, at the Alexandra Palace two thousand gas lights, costing twenty-six shillings per hour, had been replaced by six electric lamps, costing only six shillings per hour.

What undoubtedly is now wanted is the central system for the supply of the electric current in large or small quantities; and this supply obtainable on analogous terms to those required for a supply of gas. If every one wishing to use gas were obliged to purchase the necessary plant for so doing, and superintend the working thereof, we think his ardour in that direction would be considerably damped, and most probably some other method of lighting ultimately adopted. It is with satisfaction then that we note that the central system is engaging the attention of two or three most influential firms on this side the Atlantic, and we also read that one of the companies in America interested in the Brush light is about projecting a similar system there. When once a success is scored the adoption of the electric light will progress with more and more marked rapidity. The public will be satisfied with the increased light or greater economy, and those who invest their capital in electric light shares, will, we believe, have no reason to be dissatisfied with their profits.

HEINRICHS' NEW RING ARMATURE AND THEORY OF THE GENERATION OF ELECTRIC CURRENT IN A RING ARMATURE.

A FURTHER improvement on the Pacinotti* ring armature has been made by Mr. Charles F. Heinrichs, the inventor of the electric lamps with circular carbon pencils.† As this improvement is of an important nature, and possesses very promising features, we shall fully describe its principle and advantages.

Mr. Heinrichs was led to devise the new form of armature through a close study of those of the existing forms, and by observing the manner in which the electric currents are generated in them; by this he formed a theory as to the action which the soft iron ring takes in the generation of electric currents in its surrounding insulated conducting-wire. Of this theory we shall make use in this article, with Mr. Heinrichs' permission. We shall have to refer to other already known ring armatures which are improvements on the Pacinotti ring, and we shall have also to draw comparison between those and the new one of Mr. Heinrichs, without which we could not well describe its novelty and features. Several theories have been advanced to explain the part which the soft iron ring plays in the generation of electric currents in the armature, but we have not yet seen an entirely satisfactory explanation of the action which the soft iron ring takes when in motion.

M. Antoine Breguet explains the action of the soft iron ring in his small pamphlet, "La Machine de Gramme," and part of his explanations are confirmed by Mr. Heinrichs' theories, as we shall see later on; but we think Mr. Heinrichs has gone a good deal further, and has not only endeavoured to discover the disadvantages of the existing armatures, but also constructed a form of the latter in which he overcomes those disadvantages in a satisfactory and simple manner.

It is well known that when a piece of soft iron is brought with one of its ends close to a magnet (fig. 1) this piece of soft iron will become also a magnet, and the one end nearest to the magnet acquires south polarity and the other end north polarity. In the middle of the piece of soft iron a neutral line, *l l*, will be established, and if the piece of soft iron were surrounded with insulated conducting-wire, a current would be set up or generated in the same length of the wire *in one direction*. As is well

means a circuit or circuits are closed. Wires lead from the protruded conductor to any point on the line.

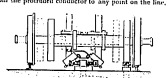

FIG. 2.

and are caused through suitable mechanism to make or break a circuit there also when required.

1156. "Magneto and dynamo-electric machines." J. H. JOHNSON. (A communication from A. de Méritens, of Paris.) Dated March 16. 4d. Consists in enabling these machines to furnish an alternate current without the employment of an exciting machine. The inductors are magnetised by the alternate current itself without the necessity for changing its direction by means of a commutator or collector. Taking the machine known as De Méritens as an example, all the coils of the ring are wound in such a manner that the exit wire from one coil is soldered to the exit wire of the next coil, and the extremity of the entering wire of one coil is soldered to the entering wire of the next coil. Hence it results that there are two entering or two exit wires leading to the binding screws where the current from the machine is collected. It also results that all the coils of the ring are traversed by one current, which changes its direction during each revolution as many times as there are coils in the ring. (*Provisional only.*)

1251. "Micro-telephonic apparatus." R. H. CUNNINGHAM. Dated March 17. 2d. An iron or steel bobbin or core, with a soft iron on the base is, after being polished with a resisting medium, coiled with a number of lengths of wire insulated and connected by one end of each length to the bobbin. The bobbin is connected with a pendulum or spring of any suitable metals, either in the form of spiral or flat springs, coated with a resisting medium, the intention being to obtain delicate vibratory motion with the object of getting electric effects with less resistance as compared with carbon as generally used. (*Provisional only.*)

1278. "Dynamo-electric machine." JOHN PEARS. Dated March 18. 6d. The object of this invention is to get a very intense magnetic field, and at the same time to have the currents generated to be continuous. In the machines of Gramme, Siemens, &c., the winding of the wire holders takes place, as nearly as possible, in the plane containing the axis of rotation. In the new invention each winding of wire on the rotating part of the machine makes a decided angle with the axis of rotation. Fig. 1 is the sectional elevation of the machine; *e f* is a shaft made to rotate; *a b* is a ring of phosphor bronze on which a great number of thin wedge-shaped coils (*c*, fig. 2) are packed so as to form an annular armature whose section is shown at *k*, fig. 2. The plane of each winding of this armature makes an angle of 30 degrees with the direction of motion when turning with the shaft. The armature is firmly fixed to the shaft, and is kept from changing its shape during rotation by means of the wooden discs, *i*, *i*, which embrace the coils on the inner parts of the ring, and which are bolted together and fastened to the shaft by the screws and collar shown in the figure, and by means of the outer rings of wood and metal, *l l*, *l l*, which are bolted together, embracing the outside of the

1284. "Telegraph wires." J. T. KING. (A communication from C. Imbard, of Pittsburgh, Pa., U.S.A.) Dated March 19. 6d. Describes a cable consisting of insulated or cotton covered wires bunched together in any desired number, and held together by a strip of cotton or other cloth wrapped spirally around them.

The interstices are filled with melted paraffin, coal tar, or similar material, or the wires are immersed in melted paraffin, coal tar, or similar material, as or before they are bunched. The cloth wrapper is then coated externally with coal tar, asphaltum, rubber, cement, or other elastic impervious material. Then, if desired, another strip of cloth may be wound on it spirally in the opposite direction, and coated in like manner. The fig. shows a cushioned bearing a box or bed, which may be of cast iron or other suitable material, preferably protected by tarring or otherwise coating the exterior. Its interior is fitted or grooved, as indicated at *b*, to form receptacles for the wire, and whole interior surface is coated with porcelain enamel, as at *c*. Upon the bed is a cover, *d*, adapted to fit within the flanges, *e*, and rest upon the shoulders, *f*.

M. DE MERITENS has completed the construction of one of his magneto-electric engines intended for lighthouse illumination. An experimental trial took place on March 23 before MM. Becquerel, Cornu, Mascart, and other members of the Technical Commission of the International Exhibition. It was proved that with fifteen horse-power his machine illuminates at once more than thirty Jablochkoff lights, and that it could, at a moment's notice, be used in a regular or for marine purposes.

THE TELEGRAPHIC JOURNAL AND ELECTRICAL REVIEW.

VOL. VIII.—NO. 186.

A NEW ERA IN PUBLIC LIGHTING.

INVENTORS are still working hard to perfect or invent dynamo machines and electric lamps, indeed it seems that at the present time this branch of electrical science is receiving more attention than all the other portions combined.

It is doubtful if *much* improvement is possible on the well known machines already in the market, unless, indeed, some great discoveries should indicate an entirely fresh direction to thinkers in that field of investigation, but this seems hardly possible.

A good lamp, simple yet effective, durable yet economical to manufacture, is, we believe, still a desideratum; but both machines and lamps are for most practical purposes sufficiently good for the electric light to have made much more rapid advancement than it can be said yet to have done.

Why then is the development progressing so slowly? The reason, we think, is partly, perhaps largely, to be accounted for by the fact that hitherto most individuals or firms desiring to use the electric light have found that to obtain the necessary plant entailed too extensive an addition to capital expenditure. And this, particularly as the advantage of the light, in point of *general economy*, when used on such a scale as for warerooms, &c., is still held by some to be doubtful. If an instance were wanting to prove the pecuniary advantage when the electric are is largely used, we might quote Mr. Swan's words in speaking before the Literary and Philosophical Society at Newcastle. That gentlemen said that, at the Alexandra Palace two thousand gas lights, costing twenty-six shillings per hour, had been replaced by six electric lamps, costing only six shillings per hour.

What undoubtedly is now wanted is the central system for the supply of the electric current in large or small quantities; and this supply obtainable on analogous terms to those required for a supply of gas. If every one wishing to use gas were obliged to purchase the necessary plant for so doing, and superintend the working thereof, we think his ardour in that direction would be considerably damped, and most probably some other method of lighting ultimately adopted. It is with satisfaction then that we note that the central system is engaging the attention of two or three most influential firms on this side the Atlantic, and we also read that one of the companies in America interested in the Brush light is about projecting a similar system there. When once a success is scored the adoption of the electric light will progress with more and more marked rapidity. The public will be satisfied with the increased light or greater economy; and those who invest their capital in electric light shares, will, we believe, have no reason to be dissatisfied with their profits.

HEINRICHS' NEW RING ARMATURE AND THEORY OF THE GENERATION OF ELECTRIC CURRENT IN A RING ARMATURE.

A FURTHER improvement on the Pacinotti* ring armature has been made by Mr. Charles F. Heinrichs, the inventor of the electric lamps with circular carbon points.† As this improvement is of an important nature, and possesses very promising features, we shall fully describe its principle and advantages.

Mr. Heinrichs was led to devise the new form of armature through a close study of those of the existing forms, and by observing the manner in which the electric currents are generated in them; by this he formed a theory as to the action which the soft iron ring takes in the generation of electric currents in its surrounding insulated conducting-wire. Of this theory we shall make use in this article, with Mr. Heinrichs' permission. We shall have to refer to other already known ring armatures which are improvements on the Pacinotti ring, and we shall have also to draw comparison between these and the new one of Mr. Heinrichs, without which we could not well describe the novelty and features. Several theories have been advanced to explain the part which the soft iron ring plays in the generation of electric currents in the armature, but we have not yet seen an entirely satisfactory explanation of the action which the soft iron ring takes when in motion.

M. Antoine Breguet explains the action of the soft iron ring in his small pamphlet, "La Machine de Gramme," and part of his explanations are confirmed by Mr. Heinrichs' theory, as we shall see later on; but we think Mr. Heinrichs has gone a good deal further, and has not only endeavoured to discover the disadvantages of the existing armatures, but also constructed a form of the latter in which he overcomes those disadvantages in a satisfactory and simple manner.

It is well known that when a piece of soft iron is brought in with one of its ends close to a magnet (fig. 1) this piece of soft iron will become also a magnet, and the one end nearest to the magnet acquires south polarity and the other end north polarity. In the middle of the piece of soft iron a neutral line, *l l*, will be established, and if the piece of soft iron were surrounded with insulated conducting-wire, a current would be set up or generated in the entire length of the wire *in one direction*. As is well

* *See Telegraphic Journal*, vol. vii., p. 219.
† *See Telegraphic Journal*, vol. vii., p. 311.

the ends of the cylinder is still not very satisfactory, the accumulation of heat on this part of the armature cannot be prevented, as all the wires of the armature cross each other at the two ends of the cylinder; and if the generator is made of a large size the length of the wire over the ends of the cylinder is increased considerably without a corresponding advantage. Mr. Heinrichs having satisfied himself on all these points, has adopted the channelled ring armature, shown by figs. 9, 10, and 11, the insulated conducting-wire being wound on the outer surface of the ring armature, lly crossing the channel with the insulated conducting-wire the inner surface of the ring is not made use of at all. This armature will give good results if made out of solid iron, or a bundle of very thick iron wire, which assists greatly in the generation of currents. This armature can be made in any size without altering its advantageous principle. It has, besides, one very great point in its favour, that is, it prevents the accumulation of the heat which is naturally produced in the insulated conducting-wires when they are traversed by powerful currents; this takes place also in all armatures through *the quick changes and* enforced demagnetisation of the iron. In Mr. Heinrichs' ring, the insulated conducting-wire which crosses the channel is freely exposed to the air, both inside and outside. This also tends to keep the iron ring cool and to maintain the efficiency of the armature. This is a point we miss in all other armatures.

In the early part of last year Mr. Heinrichs had occasion to rewind a bobbin of the multiple current generator of a London machine, and he informs us that he found the insulation of those four layers of copper wire which were nearest to the iron core totally burnt; this is prevented in Mr. Heinrichs' new armature, where the wire which is the nearest to the core has a considerable portion of its surface exposed to the air, *i.e.*, where the insulated conducting-wire crosses the channel. In fig. 10 we see this ring armature in section, made in horseshoe or channel form, the inducing magnets, n and s, surrounding the entire outer surface of the horseshoe ring in the section. Mr. Heinrichs claims as his invention the ring armature made in channel form, over which the inducing magnets, n and s, are so arranged as to surround the entire outer surface of the ring. The insulated conducting-wire in which the currents are to be generated overlies the iron ring only where the ring is directly under the influence of the inducing magnets, thus, that portion of the insulated conducting-wire which crosses the channel, and which is not under the influence of the inducing magnet, is also not under the influence of the soft iron ring. It will be seen that the length of the insulated conducting-wire which is under the influence of the inducing magnet and iron ring is much longer than the wire which crosses the channel.

It is obvious that the best results will be obtained with those armatures in which the largest portion can be brought directly under the inductive influence of the inducing magnets. Thus, if the Gramme ring (fig. 7) is made 5 inches wide it will have only 5 inches of insulated conducting-wire under the inductive influence of the inducing magnet (those which overlie the outer surface of the ring), against 1 inches of insulated conducting-wire, screened by the iron ring from the influence of the inducing magnets, as shown in fig. 5, and where no currents are generated. In the Hefner v. Alteneck armature a cylinder is 10 inches long and has a diameter of 5 inches; thus we find there are 10 inches of insulated conducting-wire for current generating against 7 inches of wire which do not generate any current; this shows favourably against the Gramme ring. In Heinrichs' horseshoe ring the proportions are 8 inches of insulated conducting-wire for current producing against 4 inches of wire which are not current producing, and these figures are arranged so as to help to keep the whole insulated conducting-wire cool. These figures show the advantage of Heinrichs' armature. In fig. 11 we show a further modification of Mr. Heinrichs' channelled ring, which we here nearly round in section, as in the original Pacinotti ring, but in which his principle of having a channel and employing surrounding inducing magnets is adopted. In another article we hope to describe the generator and the results obtained with it.

As we have shown the most developed Siemens ring armature in this article we have yet to draw attention briefly to two more modifications of *the arrangement, namely*, where the ring has been made in a flat narrow ring, and the inducing magnets arranged on both sides of the ring. The priority of this idea belongs to Mr. Schuckert,* as it was introduced in his generator over five years ago. Several of his machines have been in use in this country. The soft iron ring is made out of thin sheet iron plates which acquire little magnetism and act chiefly as a screen, as in the Gramme ring. The demagnetisation of the iron ring is much assisted by having inducing magnets arranged on both sides of the ring, but it will produce great heat in the armature.

In the Hiorth generator† the armature is also a flat narrow but solid iron ring, recessed on its circumference for the reception of the insulated conducting-wire, as in the Pacinotti ring. The position of the inducing magnets, relative to the ring, are the same as in the Schuckert generator. The ring being of solid iron, bears a great part in the generation of the currents. The enforced demagnetisation of the solid iron ring produces heat in the armature. This is to some extent overcome by a number of holes on the circumference of the ring which allow the air to circulate for cooling purposes, but produce noise when in motion.

Mr. Heinrichs' new means and apparatus for generating electric current were patented in England and abroad in November, 1879.

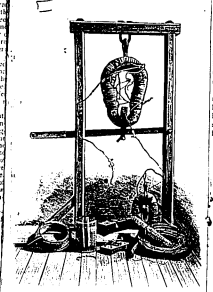
JOEL'S IMPROVED INCANDESCENT ELECTRIC LIGHT LAMP.

FIGS. 1 and 2 show an improved form and arrangement of electric light lamp recently patented by Mr. Henry V. Joel, A. M., Inst. C. E. Fig. 1 is a complete lamp suitable for lighting interiors, and fig. 2 is an enlarged section.

The improvements made in this form of electric light are mostly mechanical details, and make the

PROFESSOR HENRY'S BIG MAGNET.

In the course of his pioneer work in the investigation of electro-magnetic action, William Sturgeon, of London, discovered in 1823 that soft iron could be rendered temporarily magnetic by surrounding it with a coil of conducting wire connected with a battery. As the result of this discovery he made the first step toward the construction of an electro-magnet. He bent a piece of iron wire into the form of a horseshoe, lu-sulated it by a coating of varnish, and then



PROFESSOR HENRY'S BIG MAGNET.

wound it with copper wire spirally, the spirals being widely separated, so that the current would be compelled to pass round and round the iron core. When the current was on the wire the core was found to be magnetic; when off, the core was not magnetic.

Professor Henry took up the discovery at this point and carried it an important step further. He wound the copper wire with insulating silk, making it possible to cover the core of the magnet with a much greater length of wire in closely wound coils, and also to lay on coil above coil. The compound helix so made developed great power, the same battery yielding with it a hundred times as much magnetic power as could be obtained with Sturgeon's arrangement. The first magnet for this principle was used by Professor Henry in 1828. It consisted of an iron bar two inches square and twenty inches long, bent, of course, into the form of a U or horseshoe, and wound with full foot of insulated copper wire in nine coils. The keeper weighed seven pounds, the core twenty-one pounds, and its lifting power was 750 pounds.

This magnet was used at Albany. In 1830 Professor Henry was called to the chair of Natural Philosophy in the College of New Jersey, at Princeton. Here he made two larger magnets for use in his investigations. One weighing 59½ pounds, and capable of sustaining 2,063 pounds, is now in the cabinet of Yale College. The other, made in 1833, weighed 100 pounds, and could support 3,600 pounds. It was many years before any magnet approaching this in power was constructed.

Through the courtesy of Mr. R. H. Rowe, photographer at Princeton, and by permission of Professor Schanck, of the College of New Jersey, we are enabled to present an exact likeness of this historic instrument, as long in the frame by which the forearm tested its strength. The magnet is deposited in the hall of the School of Science, one of the college buildings erected by the munificence of the late John C. Green. The coil at the right of the engraving represents the original silk-covered ribbon coil used by Professor Henry in his experiments on induction. The wire and battery at the left are modern, to show by contrast the improvement since made in the means for electrical investigation.

In the middle of the foreground is one of the pole changers made and used by the professor. He was accustomed to delight himself and his classes with this by changing the polarity of the big magnet so quickly that a twenty-eight pound armature could not fall off, but was freed and reattracted to its place with a sharp snap.

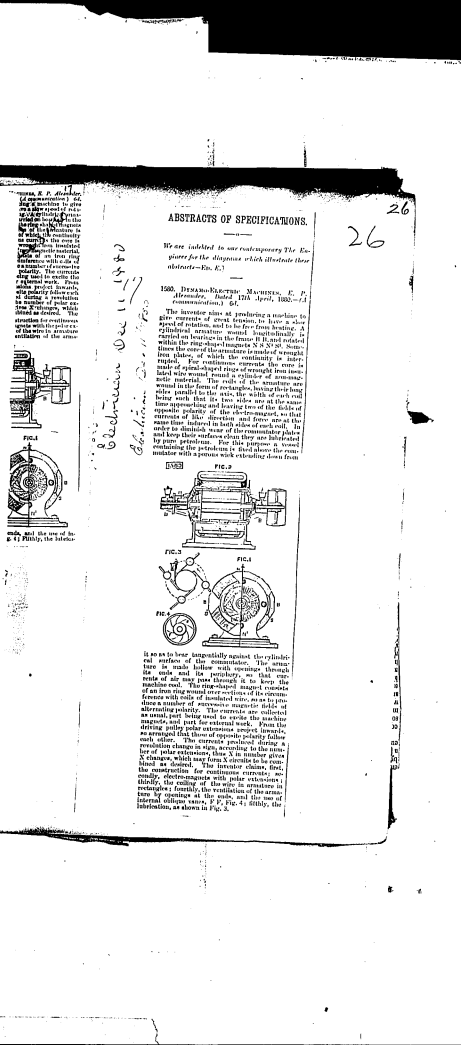
ARTICLES.

THE NEW ELECTRIC MOTOR.

A DESCRIPTION of the new electric motor about which we have heard rumours for some time, has been published at last by the inventor, in the shape of a paper read before the Franklin Institute, and illustrated by a working model, which, in the opinion of experts, clearly demonstrated its utility. This model, which weighed only 23lbs., was connected with a sewing-machine, which did both light and heavy work, the speed being quite under control, with a current estimated at two Webers per second, the power generated being 1,000 foot-pounds. The battery used was a comparatively simple one of six cells, each containing a zinc plate 6in. long by 2in. wide; but at present we have no account of the consumption of zinc and chemicals, which, however, must be obviously more expensive than a steam or gas engine in producing current, though the batteries have the great merit of convenience and adaptability to household requirements. One of the earliest inventors of a really practical electric motor was Prof. Jacobi, of St. Petersburg, who, in 1835, at the expense of the Czar Nicholas, constructed an electric engine. For four years Jacobi experimented with his engine, and at last he succeeded in driving a large-sized boat (an ordinary 12-seater) at a speed against the swift current of the Neva, at the rate of three miles an hour. To accomplish this feat, however, he employed a battery of 64 cells, which contained many square feet of platinum, and Jacobi was characterised by the meagre results of his labours, although, as we know now, he was on the threshold of an important discovery. His engine was excellently designed, and was possibly as good as any that followed it, until Gramme in 1870 discovered that his dynamo machine could be made to act as a motor. Writing then to Faraday in 1839, Jacobi said that the most important object in the application of electro-magnetic machines had always been the management of the battery, but that obstacle "existed no longer," for he hoped within a year to have an electro-magnetic engine of from 40 to 50-h.p. Jacobi had at this time discovered that his form of platinum-coated cell was of 50 square feet of platinum surface to obtain one h.p., but he suffice in future. Jacobi was disappointed it is needless to say, as were those who followed in his footsteps, and when Joule demonstrated the principle of the conservation of energy, and it was found that the consumption of zinc in the battery was nine times as costly as the consumption of coal in the furnace, the idea of making electricity commercially available for industrial purposes was temporarily abandoned. Innumerable engineers and other sanguine inventors, according to Mr. Grisom, those who forthwith tried to produce an electric motor brought to the consideration of their work a wealth of ingenuity and all the learning of all the sciences save one, electro-magnetic induction,—and like other inventors who have gone before him, he indulges in some chirrup cheers at the scientific men who con-

tended that electricity produced by the consumption of zinc could never compete with steam. The purpose of his paper, he tells us, is to collect facts which will show that this conclusion is erroneous; but, as will have been expected, he fails to prove anything of the kind: for he steers wide of the question by attempting to show that if manual power is 100 times as costly as steam, it is at least eleven times as costly as electricity, and because manual power is preferred for certain work to steam, so he thinks electricity will supersede steam eg. in the case of sewing-machines. Of the two classes of electric motors, those which utilise the attraction of an armature to an electro-magnet, are wasteful of electric energy, because the residual magnetism retards the backward movement of the armature; but those which utilise the attraction and repulsion of two or more magnets, convert a portion of the retarding influence, of the residual magnetism, into a useful force. To test, says Mr. Grisom, all dynamo-electric engines, when used as motors, convert all magnetic resistances to motion into a counter electromotive force. It appears that this counter force retards the consumption of zinc in the battery, and tends to depolarise the negative plate. Counter electromotive force is usually regarded as increased resistance, says Mr. Grisom, but an experiment with one of his motors demonstrated the error of that view; for, after being held unmoved, while a sufficiently powerful current was passed through its coils, and the deflection of a tangent galvanometer carefully noted, it was found, on allowing the motor armature full speed, that the galvanometer indicated about a fourth of the original amount of current. The electro-motive force of the battery was practically reduced when the speed of rotation was diminished by a brake, the needle immediately indicated a greater current. Unfortunately, no illustrations and very meagre details of this motor accompany the paper, though a small one, as mentioned above, was shown at work. It is an efficient dynamo-electric machine, as well as motor, and its essential advantage over the older forms is in the field-magnets, which are of so peculiar a shape, that all the magnetic lines of force are brought into the best possible position for effecting the revolution of the magnetic armature. According to Mr. Grisom, the secret of his motor lies in the following:—Mr. Ladd, he says, claims to have discovered the great advantage possessed by the lines of force of a helically circular magnet over those in the usual "bow-shape form;" but does not appear to have attempted to utilise the lines of force which fill the interior of a curved magnet, from the neutral to the polar points. If a bar of soft iron is pivoted at one end, so as to move in a horizontal plane, and a semicircular magnet is placed concentrically with the circle which the bar can describe, it is found that a given force is exerted upon the bar, at a much greater distance from the poles, when the latter is within the semicircle, than when it is without. I believe that no field magnets on this principle have ever been constructed, and herein is the secret of the power of this little motor, which weighs about 23lbs., and which compares favourably with those of the old forms of 15 times its weight." An electric motor would, however, find a scant welcome in a house, unless the motor is free from odour, trouble, and noise. Grisom's is, it appears, inclosed in a waterproof box, does not require commutated acid, gives out no odour, does not exhaust itself, and requires removing only when the fluid is used up by actual work. It requires absolutely no attention until the reservoir is exhausted by actual work. A great deal of unscientific "mystery," or obscurities of explanation, surrounds the whole invention at present; but it is clear that the battery is simply made up of six very deep bichromate cells, in which the deposits of salts set up currents, which constantly bring fresh liquid to the plates. In answer to questions, Mr. Grisom said that of the zinc plates were 6in. by 2in., with two carbons to each zinc, and each cell held about a gallon of solution, so that if the motor is small, and "can be really considered," the battery would make quite an article of furniture. Upon a point in connection with the machine was specially mentioned by the inventor, and that was the fact that pressure is applied equally to both sides of the shaft at once, thus reducing wear to a minimum, the weight of the armature and the tension of the belt being the only causes of friction. The bearing is four diameters of the shaft, and no amount of wear can bring the poles of the armature and magnets into contact. The motor is about 9in. long by 2in. or 3in. in diameter, and as shown, was carried on an iron fork, attached to the back of the table of the sewing-machine. The latter was run at a speed of 800 stitches per minute, but by pressing on the treadle of the machine, the plates are raised in the battery, and the speed can be controlled down to 20 stitches per minute, while the power is sufficient to sew through leather, or as many folds of linen as will go beneath the foot of the machine. The motor is not yet ready for the market, which may possibly account for the meagreness of the information—somewhat in a scientific paper—but we have the principles on which the machine is constructed, and must wait for further details, as also for some data as to its running cost, for it may be doubted whether six plates of zinc 1in. by 2in., will "suffice for the sewing of a small family, for one year," especially if they have much leather work. It will be understood, however, in what way the new motor competes with steam—way a motor for a sewing-machine in places where no sensible power would have a steam-engine and its boiler. As so small a motor will run a sewing-machine, one a little larger will run a lathe, and soon; hence there will be a considerable demand, if only the motor is cheap, and Otto little to work.



Engraved by Messrs. Bagshaw, Bentley Street, Shadwell, London, from whose block this illustration is printed.

ABSTRACTS OF SPECIFICATIONS.

We are indebted to our contemporary The Engineer for the diagrams which illustrate these abstracts—Ed. E.M.

1560. DYNAMO-ELECTRIC MACHINES. *E. P. Alexander, Dated 17th April, 1880.—1 communication.* 6d.

The inventor aims at producing a machine to give currents of great tension, to have a slow speed of rotation, and to be free from heating. A cylindrical armature wound longitudinally is carried on bearings in the frame B B, and rotated between the poles of field magnets N S N S. Sometimes the armature-armature is made of wrought iron plates, of which the quantity is determined. For continuous currents the core is made of spiral-shaped rings of soft iron, and insulated wire wound round a cylinder of annealed iron material. The coils of the armature are wound in the form of a bangle, having their long sides parallel to the axis, the width of each coil being equal to the distance between the centres of two opposite and adjacent poles, leaving two of the coils of opposite polarity of the field magnets, so that the currents of like direction and passing at the same time induced in both sides of each coil, may unite in the middle near one of the commutator plates and keep their surfaces clean as they are lubricated by the oil-cups. For this purpose a vessel containing the petroleum is fixed above the commutator with a pipe and screwing down from

it so as to bear tangentially against the cylindrical surface of the commutator. The armature is made hollow with openings through its ends and its periphery, so that current of air may be forced through it by keep the machine cool. The wire-shaped magnet consists of an iron ring wound with insulated wire, in connection with coils of insulated wire, so arranged as to produce a number of successive magnetic fields of alternately opposite polarity. Coils are collected as usual, part being used to excite the machine and the other part for external work. From the driving pulley polar extensions project inwards, so arranged that the magnetic polarity follows each other. The current produced during a revolution change in sign, according to the number of polar extensions; thus X in number gives X changes, which may have X circuits to be used as desired, each having the armature coils, the commutation for continuous currents; so-called "multiple arc" coils, with polar extensions; thirdly, the coiling of the wire in armature in rectangles; fourthly, the variation of the armatures by openings at the ends, and the use of internal oblique vanes. F F, Fig. 1, shows the lubrication, as shown in Fig. 2.

Engraved by Messrs. Bagshaw, Bentley Street, Shadwell, London, from whose block this illustration is printed.

up by the chain, C, allows the carbon to drop on the lower rest, thus making full contact; when the keeper is again attracted, and pulls the lever and holder up again, the small weighted lever and rests descending and holding the carbon tight.

The lower and negative carbon is held in an upright tube, having a spiral spring, H, which propels the carbon upward. The spiral spring is held down by a chain, H, which is attached to R; the other end being wound on a barrel to which an escape wheel, J, is fixed, and which is released tooth by tooth by the lever, K, and pallets, K', carry line; the keeper attached to the lever, K, moves up and down. N is a rod to convey the current to the lower carbon. N N are the binding screws or connections. It will be seen that this lamp preserves the focus of light always at one point.

The lamp as shown is calculated to burn five hours, and gives the light of 1,000, with about 4-horse engine power.

FITZGERALD'S MAGNETO AND DYNAMO ELECTRIC MACHINES.

THE improvements in magneto and dynamo electric machines to my illustrate are the invention of Mr. Desmond G. FITZGERALD, and deserve careful attention, inasmuch as they show a decided advance in the right direction. The main idea of the inventor seems to have been to aim at perfecting the Gramme machine, and so, instead of making the ring between the poles of a magnet on the ordinary system, he wholly or partially surrounds the ring both longitudinally and transversely, that is, in two different inductive sections. The ring is thus magnetized directly and with the least possible loss, and the direction of the inducing magnetic polarity is in the circle constituted by the ring itself, as it should be.

Fig. 1 shows a transverse sectional elevation of a dynamo-electric machine, Fig. 2 is an elevation partly in section looking on to the left-hand side of Fig. 1, with the driving pulley removed. In Fig. 1 A is the soft iron ring carrying the coils, more or less, each, B, of insulated wire, all wound in one direction. The ends of these wires are all wound in one coil, C, on the boss, D, of the ring, A, with its coils, connected to the suitable bindings on a boss, E, to the commutator, F, mounted on a ring, the driving pulley, H. The standards, G, G, and at one end carry the bearings for the shaft, I, which, at one end carries the commutator, F, and at the other end the driving pulley, H. The commutator, F, is shown in Fig. 3, and consists of insulated steatite segments, A, in which are fixed the metal portions, of which the ring, I I, is composed, and B B are the brushes, of which two pairs are used—one pair of the largest diameter, I, the division between the halves being preferably at the top and bottom. The separate portions of this brush are insulated from each other, and the ends of wire are so connected two magnets are wound with coils opposed as the vertical plane traverses the ring, A. The reverse direction of the winding near the poles required to produce this effect is shown at Fig. 3. The various sections of the electro-magnetic ring are united and held in position by thin lugs, J, projecting from their cores between the coils of wire. These lugs, J, are bolted to other lugs, K, cast on the frame, L. The ring, A, has preferably a deep recess, a, cut in it circumferentially, as shown. The collector, C, consists of a cylinder of wood or other non-conducting material rightly attached to the boss, E, and having let into its inner circumference a series of strips of conducting material, M, insulated, and in number equal to the coils of ring, A. The extremities of the coils are brought to the outside of the collector, and connected so as to form a closed circuit, the points of connection between adjacent coils being severally brought into contact with the conducting pieces, M, as shown at m m. Fig. 4 shows clearly the collecting brushes, the current being taken off at the horizontal neutral line, or the line of greatest polarity. Fig. 4 also shows a front view of the collector, C. The brushes are flat springs, one, O, each having at one end a contact piece, O, and being attached at the other end to a screw, P, passing through a terminal, Q, and being fixed in position by a set screw, R. A short lever, S, is fastened to the end of the bar, P, having an adjusting screw, S', jumped through it, and bearing on the plate underneath. This screw enables any required tension to be put on the springs, O', thus regulating the contact friction. The terminal, Q, is fixed to and insulated from the standard, G, and connected to the binding screw, T, of the machine. The weight of the current collecting portion of the machine is liberated by means of these springs.

Considerable modifications are made in the construction of the ring. The method of construction is shown by Fig. 5. Ordinarily, in winding a number of coils of wire upon a ring, more especially if it be of circular section and if the

number of turns of wire be the same in each layer, inter
stices are left between the coils. The interstices are filled
by Mr. Fitzgerald with soft iron wedge-shaped blocks, V.
These blocks can either be made with the ring, or separately
and slipped on, the ring being made in halves to receive
them, as shown.

Fig. 6 shows a modified form of the ring, A, and the en-
circling magnets, I P P, the ring being cylindrical instead
of circular, and the encircling magnets also being modified
shapes to correspond. The principle is the same whichever
form is used. Figs. 7 to 10, however, illustrate a modifica-
tion in which the ring, A, is wholly encircled on its cross
section by coils, W, in lieu of inducing magnets.

Fig. 7 is to illustrate a totally new form of machine in
which the ring, A, is wholly encircled on its cross section by
coils, W, and, also, in lieu of inducing magnets. These en-
circling coils, W, are supported in a suitable framing, X, and
the ring, A, is made to rotate through them, is mounted between
three or more rollers, Y, by one of which—preferably the
upper—it is driven by frictional contact, the surface of the
The extremities of the coils of ring, A, are attached in a
manner similar to that before described to a series of strips
on cheeks or wooden ring, A², let them into the external surface of
ring, A. The current is taken off as an apparatus on the
outer circumference of the coils, W, left in such a way as the
the coils of wire Preferably, the coils, W, left in such a way
to leave a longitudinal groove, W, on the inner surfaces,
where they pass over the ring, A, on the outside of ring, A.
This shows of the two surfaces of the ring and encircling
coils being brought into very close contact. Fig. 8 is a
transverse section taken at e f, Fig. 9 is a vertical plan of
ring, A, at center line, and Fig. 10 is a section of coils, W,
taken at line, e f, Fig. 7.

It is obvious that in the three forms of machines shown
permanent magnets may be substituted for the electro-
magnets, the permanent magnets rotating substantially the
same as the electro-magnets, but being necessarily divided at the polar-
ities. Their similar poles are connected.

Both the ring, A, and the coils on the inducing electro-
magnets, I P P, or the inducing coils, W, left in such a way
that one or more in series, as is well understood. The ap-
paratus may be advantageously constructed in duplicate, the
halves of the hollow electro magnets, I P P, being employed to ang-
ize both sides of the ring, A, before employed to ang-
ize for the external portion of the circuit being taken
off the several rings, A. The coils being taken
divided in a ring of soft iron provided with a circum-
ferential slot to allow of the passage of the wires. Such
coils, W, is applicable to the electro-magnets, I P P.
Fitzgerald—of double or single curvature, as may be called for.
The subject suggests—Scientific American.

HORTICULTURAL NOTES.

LIQUID MANURE FOR GRAPES.—The *Rural World* de-
scribes a small vineyard belonging to Mr. Peschel of Her-
man, Mo., consisting of an acre and a half of vines, mostly
Elvira and Norton's Virginia, with fewer Delaware and
Ohland. He feeds these vines heavily with liquid manure
dited in the season about the blooming period and again
when the stoning process commences. Small furrows are
made above the vine, into which the manure passed about
the furrows covered as soon as the soil has absorbed it. The
editor states that "he has astonishing results, for four years
having an annual return of about $700 from this small piece
of ground, and his crop was really wonderful this year." No
estimate is given of the cost of cultivation.

MARKETING FRUIT.—The *Rural Home* says that most of
the money paid for fruit by consumers in Rochester goes to
the middleman. Concord grapes have been sold by the
growers at one and a half to two cents per pound. The grower

Edison's New Machine.

Mr. Edison has just completed a very powerful dynamo machine, which was tested recently with satisfactory results. It is 180 horse power, and consumes 400 pounds of coal an hour, at an aver-age cost of $2.50 a ton, screenings being used, making the cost of running it about fifty cents an hour for 1,200 lamps. The armature is made of copper bars, one-half inch thick, instead of small wire as usual. The maximum of illuminating capacity is equal to 537,000 candles. The cost was $60,000. The largest machine previously built by Mr. Edison was an eight-horse power ma-chine of sixty lights, with two magnets weighing 300 pounds each. There are twelve magnets in the new machine, weighing 685 pounds each. It is de-signed for a station at Charing Cross, London, where a number of houses are to be wired for lighting by this means. Mr. Edison intends to build twenty-four machines of 250-horse power each, twelve of which will be placed in the Pearl street station, to light a district wherein 7,000 lamps have been wired, which will be lighted by 15,000 lamps.

De cette façon on pourra envoyer régulièrement un courant à chacune des oscillations de celui-ci, et obtenir les mêmes effets que M. Voûté a si bien réalisés.

Dès lors, l'horloge-type synchronisera le pendule conique par le procédé ordinaire, et celui-ci, l'horloge à régler, par un supplément de rouages.

G. TRUCK ET ROBIN.

L'ÉLECTRICITÉ
ET LA LOCOMOTION

La traction des véhicules par l'électricité constitue, suivant le point de vue auquel on l'examine, une application d'une immense avenir ou une réelle utopie, dans l'état actuel de nos connaissances.

Nous avons parlé à plusieurs reprises dans ce Journal de l'application de l'électricité à la traction des petits chemins de fer dans les villes, soit par voies aériennes, soit par voies souterraines. Ce système de traction dont les avantages sont connus, recevra sous peu son application en Amérique, en Allemagne et en France; le question est étudiée de tous côtés et avance à grands pas vers sa réalisation pratique.

Il s'agit seulement, dans l'espèce, d'une transmission de force à distance, cette force étant produite d'abord par des moteurs à vapeur fixes et restituée ensuite avec un rendement relativement élevé, tel le producteur d'électricité est fixe et le moteur seul, le récupérateur est mobile, ce qui diminue dans une certaine proportion le poids mort transporté et le rend, pour des petites forces, bien inférieur à celui de locomotives à vapeur qui, pour de grandes puissances, remorquent tous leurs avantages au point de vue de la légèreté. C'est donc, comme l'a démontré M. Marcel Deprez ici même, aux petits chemins de fer, aux tramways et au service du transport des dépêches qu'il faut réserver l'emploi de l'électricité.

Si, au contraire, il s'agit d'employer l'électricité à la traction des tramways ou des voitures particulières en transportant avec soi le générateur électrique, l'idée devient manifestement irréalisable, et nous nous proposons de le démontrer par quelques chiffres. On doit, en effet, s'adresser dans ce cas aux piles à liquides; nous ne citons que pour mémoire les piles thermo-électriques qui, jusqu'à présent, n'ont fourni que des quantités d'électricité hors de proportion avec leur poids et leur volume.

Ce que nous nous proposons d'établir ici paraîtra bien évident à la plupart de nos lecteurs, mais n'est pas absolument prouvé pour tous, et nous pourrions citer telle personne qui cherche actuellement les moyens d'appliquer la pile de M.... — notre discrétion nous empêcher de le nommer, — à la traction des tramways.

Quelques chiffres vont nous montrer toute l'impossibilité de cette application.

Supposons un tramway pesant, voitures, piles, moteur et poids utile, cent-kilos voyageurs, tout compris, 4000 kilogrammes. L'effort de traction sur un tramway, en palier, dans les conditions ordinaires, est de 10 kilogrammes par tonne, soit 40 kilogrammes pour le poids total. A une vitesse de 2m,50 par seconde, c'est un travail de 100 kilogrammètres que doit fournir le moteur. Avec une rampe de un centimètre par mètre, le travail se trouve doublé, soit 200 kilogrammètres par seconde.

C'est ce dernier chiffre que doit pouvoir fournir le moteur en pratique pour que, s'il se présente une rampe plus forte, 2 centimètres, par exemple, il puisse fournir un travail suffisant en ralentissant sa vitesse.

La pile électrique la plus puissante actuellement connue, eu égard à son poids, son volume et la somme de travail disponible, est la pile Bunsen, modèle Ruhmkorff.

En admettant pour le modèle en question un poids de 3 kilogrammes, une force électro-motrice de 1, 8 volts et une résistance intérieure de 0,06 ohms, on trouve que le travail extérieur total représente 1,128 kilogrammètres par seconde.

Mais il ne faut pas perdre de vue que la moitié seulement de ce travail extérieur total peut se convertir en travail utile. Chaque élément pesant 3 kilogrammes, pour donc fournir un travail théorique maximum de :

$$\frac{1,128}{2} = 0,564 \text{ kilogrammètres.}$$

Il suffirait donc, d'après ces chiffres, de placer sur le véhicule 200 éléments Bunsen plats, modèle Ruhmkorff, pour fournir l'électricité suffisante à la mise en marche du tramway de 4000 kilogrammes.

En pratique, les frottements propres du moteur, des transmissions, les mauvais contacts, la polarisation des piles, les résistances des conducteurs, etc., augmenteraient ce chiffre dans de très-grandes proportions, et l'on arriverait, pour pouvoir marcher sûrement à ces vitesses, au chiffre de 500 éléments.

Ces éléments à 3 kilogr. représentent déjà un poids de 2500 kilogr. sans les accessoires. Il ne reste donc plus que 1500 kilogrammes pour le véhicule, la machine motrice, les transmissions et le poids utile!

Avec d'autres piles, telles que la pile Reynier, par exemple, dont le travail disponible est environ moitié moindre, on arrive au chiffre de 1000 éléments pour produire la progression du tramway de 4000 kilogr. à la vitesse indiquée ci-dessus, et le travail utile reste nul.

L'un pourra, il est vrai, diminuer la vitesse et par suite le travail dépensé, mais au-dessous de la vitesse indiquée, — 2m,50 par seconde, — ce qui, avec les arrêts obligés, ne représente pas plus de 6 kilomètres par heure, le tramway ne peut plus rendre aucun service. On ne trouve donc entre deux alternatives également insolubles avec les piles connues qui, en outre de leurs inconvénients personnels, tels que dégagement de vapeurs nuisibles, prix énorme du zinc qui sert de combustible, etc., sont encore beaucoup trop lourdes et trop encombrantes eu égard à la somme d'énergie qu'elles mettent en jeu dans un temps donné.

de la lumière électrique, a montré tout le parti qu'on pouvait tirer de ces sortes de piles, jusque-là affectées seulement aux expériences de physique.

Ce court résumé des travaux effectués en France depuis une trentaine d'années montre que nous nous sommes toujours non-seulement maintenus à la hauteur des progrès qui se sont accomplis dans les applications de la science électriques, mais encore que nous avons une très-large part dans ces progrès eux-mêmes.

THÉ. DU MONCEL.

ÉTUDE
SUR LES ÉLECTRO-AIMANTS
CONSIDÉRÉS COMME ORGANES DE TRANSFORMATION D'ÉNERGIE

3e article (voir les nos des 15 mai, 15 juin, 15 juillet, 15 août, 15 septembre, 1er octobre et 1er novembre).

L'examen du tableau qui, dans notre dernier article, renferme une classification rationnelle des transformateurs électro-électriques par induction, donne lieu aux observations suivantes.

Nous avons déjà indiqué comment les transmetteurs téléphoniques sans pile devraient être partie de ce tableau. Il est à remarquer de plus qu'ils doivent être rapprochés des machines telles que celles de Page, Breton... etc., car dans ces machines l'inducteur est réellement l'aimant dont une armature en fer doux en mouvement fait varier le magnétisme, et l'induit est la bobine qui recouvre les pôles de l'aimant.

Enfin, il est à remarquer aussi que le tableau précité est encore incomplet, il y a de nombreuses variétés possibles qui n'existent pas encore : ce sont des vides à combler ; il y remédier, soit en produisant de nouvelles machines, soit en transformant les anciennes.

IV

TRANSFORMATION INDIRECTE, PAR L'INTERMÉDIAIRE D'UN CHAMP MAGNÉTIQUE, D'ÉNERGIE ÉLECTRIQUE EN ÉNERGIE MÉCANIQUE.

Nous arrivons à un dernier emploi des électro-aimants qui n'est pas le moins important, et qui est, ou peut le dire, actuellement à l'ordre du jour. Il s'agit de la transformation, inverse de la précédente, d'énergie électrique en énergie mécanique.

Nous avons donné dans nos articles précédents de nombreux exemples de transformations directes de ce genre obtenues en se servant de courants intermittents quelconques ou de courants ondulatoires. On peut faire ici une subdivision analogue, et ranger les appareils ou machines dont nous nous occupons en ce moment dans deux catégories : l'une où l'on utilise des courants quelconques, la seconde où l'on emploie des courants intermittents très-égaliers dits *ondulatoires*.

PREMIER CAS. — *Utilisation de courants quelconques.*

[A]. — *Production de mouvements continus.*

Les machines susceptibles de produire ce résultat sont bien connues de nos lecteurs. Ce sont principalement les machines électro-électriques par induction transformées en moteurs en vertu de leur réversibilité. Tout le monde sait que dans une machine telle que celles de Gramme ou de Siemens, à travers laquelle on fait passer un courant, la partie mobile se met immédiatement en mouvement et l'on conçoit sans difficulté que ce mouvement puisse être transformé en force à l'aide des mécanismes ordinaires, ou transmis au loin par intermédiaire de câbles, de courroies... etc. De là les applications remarquables qui sont tentées en ce moment : labourage par l'électricité, machines-outils mues par elle, chemins de fer électriques... etc., etc. Ces essais ont été et sont tous les jours dirigés dans ce Journal, témoin les articles de M. M. Deprez sur les locomotives électriques ; il est inutile de parler ici de ces différentes applications, il suffit de constater que la plupart des machines électro-électriques par induction peuvent être, au moins théoriquement, transformées en moteurs, et c'est à la pratique de déterminer celles qui peuvent être le mieux appropriées aux usages particuliers qu'on en veut faire ; car il est infiniment probable qu'un type de machine unique ne pourrait satisfaire en même temps à ces usages divers.

En tout cas, il est certain que les moteurs électriques ont devant eux un avenir assuré, et l'on peut bien affirmer, sans être taxé de témérité, que dans peu de temps ils entreront dans la pratique industrielle : on conçoit donc l'intérêt qui s'attache à cette récente application des électro-aimants.

[B]. — *Production de mouvements alternatifs.*

En dehors des moteurs électriques proprement dits dans lesquels la constante du mouvement est en général une condition essentielle, on peut concevoir qu'un puisse, en se servant de courants électriques intermittents alternativement de sens contraires, produire dans un champ magnétique invariable, des mouvements alternatifs identiques.

L'action d'un champ magnétique sur un courant dépend en effet du sens de ce courant, et l'on peut combiner la nature du champ et le sens du courant de façon à obtenir le mouvement que l'on désire.

Je ne citerai qu'un exemple remarquable de ce genre de transformation : celui qu'offre le relais de M. Hughes.

Ce relais a été imaginé pour pouvoir transmettre des signaux télégraphiques à l'aide de courants extrêmement faibles, tels que ceux qu'on peut faire passer par exemple à travers un câble sous-marin présentant un grave défaut.

Il se compose d'un gros électro-aimant, semblable à celui de Faraday pour l'étude de la polarisation rotatoire magnétique, animé par un courant, et dont les pôles très-rapprochés forment un champ magnétique très-condensé. Dans le plan vertical des pôles, aussi près d'eux que possible, une lame d'or très-mince est suspendue dans une petite cage de verre, entre deux tiges métalliques. Il est facile de voir que si

THE TELEGRAPHIC JOURNAL AND ELECTRICAL REVIEW.

VOL. VIII.—No. 189.

THE PHOTOPHONE.

THE discussion on the paper read on the 8th instant before the Society of *Telegraph Engineers* has gone far to confirm an opinion we expressed in our leading article published in our issue of the 1st November. We there stated that we doubted the accuracy of the conclusions drawn by Professor Bell with reference to the action of light upon matter; and the experiments made by Professor Tyndall seem to have conclusively proved that the effects observed are due to heat and not to light. We do not in the least desire to depreciate the work of Professor Bell; the experiments he has made are in the highest degree interesting and worthy of praise, though the cause of the effects produced may have been misapprehended.

According to Professor Tyndall the sounds produced are probably due to the alternate expansion and contraction of the particles of which the matter is composed under the influence of heat. The experiments are valuable in that they show with what great rapidity changes of temperature may be effected. In the case of the telephone it is shown with what great rapidity magnetic changes can take place.

It is well known that an ordinary electro-magnet takes a comparatively considerable time to become thoroughly magnetised, and an equally long time to become completely demagnetised. Similarly, any kind of matter takes a considerable time to become sensibly heated, and the heat is lost equally slowly. In the two cases we have referred to we have the changes taking place with great and unexpected rapidity. Where the changes are minute the rate of action is correspondingly rapid, and it seems probable that this is so in every physical action; in the case of the action of light upon selenium we have these rapid changes taking place. These facts seem not unlikely to have a considerable bearing upon the question of fast speed working on submarine cables; possibly by signalling by very minute changes in a current a corresponding high speed of transmission may be attained. We do not suggest any means of effecting the object, but we think that there is a field for inquiry in this direction.

MAXIM'S DYNAMO ELECTRIC MACHINE ARMATURE.

THE armature, the invention of Mr. Hiram Stevens Maxim, of Brooklyn, America, is shown by figs. 1 to 5.

The body of the armature is constructed of thin plates of iron of the form shown in fig. 1, and at A', in fig. 2.

These plates should be of the best annealed iron, and are provided with a series of "radial" projections which serve as pole extensions. Part of the plates of the armature are made of the form shown in fig. 1, and at n^1, in fig. 2. These are provided with longer projections corresponding to the "radial" projections of the other plates, and also with additional projections both on the outside and on the inside for the purpose of holding the wire of the coils in position. An armature is constructed by placing a sufficient number of plates alongside of each other, and fastening them together by means of pins or rods, n^2, n^3, made of some diamagnetic material passing through all the plates, as shown in fig. 2. The plates, however, are not placed directly in contact with each other, but are separated by washers upon the rods, n^2, n^3, of about the thickness of the plates, and interposed between them, or between pairs of them, so as to leave air spaces between the plates. Where the tension of the current is very great, as in machines for supplying electric lamps, the larger plates are made of some strong insulating material, a few of them, say, one to each end, and one in the middle being used, and they are made to project so as to keep the wire at some little distance from the iron and prevent all danger of a short circuit.

Where a current of low tension is required, all the rings are made of metal, and it is advantageous under some circumstances to use more of the larger or even to construct the whole armature of them. The manner of winding the coils is shown in figs. 1 and 2, where c^1, c^2, represent the coils wound upon the armature and held in position by the projections on the large plates, n^1, so as to leave air passages between the coils, both upon the inside and upon the outside. The armature is attached to its shaft by means of a hub and is made to fit into the rings, or by any other suitable device. It is important, however, that the space between the armature and its shaft should be left substantially open, so as to permit the free passage of air. A sufficient number of the plates shown at n^1, having the larger exterior and interior projections, should be used to keep the coils separated throughout their entire course, so as to leave no close passage for air between them. In order to secure the greatest advantages from this construction, the plates composing the armature should be made thin, and a considerable number of them used.

To obviate a sharp bend at the end of the coil, and the consequent injury to the insulation and increase of resistance, the end rings of the cylinder are constructed of half-round iron; this presents an easy curve for the wire at all points.

In other respects than those mentioned, the armature is similar in construction and operation to those which are now well known and in common use.

NEW ELECTRIC MOTOR.*

BY WILLIAM WOODNUTT GRISCOM.

(CONTINUED FROM PAGE 93.)

By way of illustration, the application of human energy to the sewing machine is not only a false economy, but has proved the cause of many new and painful diseases in female operators, which annihilate their lives and affect the physique of their offspring. If any motor can be substituted for human energy in this field, there can be no greater or more convincing consideration offered to invite attention to it.

The sewing machine is in almost every home, and the needs of these discuss are spread in every class of society. The comedy, as before mentioned, is a home-held motor, and it was natural to suggest a small steam engine for this purpose; but steam is unsuited to this end, because—

1st. It requires time and trouble to start it to work, and a busy housekeeper, who may need, perhaps, to do five minutes of sewing, has no time to waste.

2nd. It is always liable to explode, or to burn out the boiler, or get various portions of its complex mechanism out of order, so as to require an experienced engine driver to repair it.

3rd. It emits an offensive odour of lubricating oil, and vitiates the atmosphere with the products of combustion.

4th. It is really much more expensive than these steam engines from which our calculations were made. If gas is consumed for a household engine the fuel amounts to from twelve to twenty-five feet of gas per hour, costing for a motor giving one thirty-third of a horse-power as much as the fuel of a six or twelve horse-power steam engine.

This last consideration would not weigh with the actual sufferers of the acute forms of disease, but the other objections are serious, and apply to all heat-motors, such as gas, steam, and caloric engines.

Other motors are before the public—the various hydraulic motors which require the special introduction of water-pipes and waste-pipe, and entail yearly visits from those friends of humanity, the plumber and the tax-collector. Then there is the spring motor, which you wind up every quarter of an hour or so, (depending, of course, much more power is the winding than you get out of it in work, and which has an unhappy habit of bursting its bonds occasionally, and wasting its short store of energy where it is least needed. Then there is the curious clock-work motor, mechanism is connected with the seat of the motor, whose various levers, cogs, cams and chicks to the top of the chair, and by the rest of the chair gradually winds up the strong spring, thereby the weight of the operator, driving the sewing machine the meanwhile. The operator then runs the sewing machine for and the performance is renewed. A very good speed can be attained by rising and sinking forty times per minute.

It is now fair to examine the theoretical and practical objections to electric motors, first with batteries. They may be divided into two classes—those which utilise the attraction only of the clock in the institute library, and those which utilise the attraction and repulsion of magnetic systems, and these which utilise the former act by intermittent attraction only, and are wasteful of electric energy, because the residual magnetism, during the interruption of the current, retards the passage of the armature away from the pole which had just attracted it.

Those of the latter type, however, recover a portion of the retarding influence of the residual magnetism into a useful force; in fact, all dynamo-electric generators when used as motors consume little magnetic resistance to motion into a counter electromotive force. At first glance it seems strange to consider a consumption of zinc in the battery and leads to be dependent on the negative plate. It has been usual to regard this counter electromotive force as an economy, but in point of fact it retards the motive force as increased resistance, but a simple experiment will show the error of this view, and will at the same time demonstrate that economical motors must also be the same dynamo-electric machine in order to recover this force, which would otherwise be lost. A small motor of the form, which is was held motionless while a sufficiently powerful type before you any of four velocity per second—viz., a current—and a galvanometer was also in circuit, whose deflections was carefully observed. Then, without changing the connections, the motor was allowed to run at full speed, when the galvanometer indicated about one-fourth of the original amount of current. The electromotive force of the battery was practically constant, and, therefore, according to the formula

$$\text{Electromotive force} = \text{Resistance} \times \text{Current}$$

the galvanometer should have indicated the same current as at

* Paper read before the Franklin Institute Nov. 17th, 1880.

first, unless the resistance had been changed or a counter electromotive force produced. The speed of rotation was then diminished by a brake, and the needle immediately indicated a greater current. This is in direct conformity with the well-known law that the electromotive force of a dynamo-electric machine varies with the speed of rotation, whereas the resistance of a coil is not affected by mere motion.

A still more striking proof that the "back-pull" of residual magnetism may be converted usefully into electricity is exemplified in a motor constructed more than a year ago by the writer on the same principle as this one, save that the fields are free, but connected with the armature. The current of the battery is sent through the armature, which revolved with considerable rapidity. If the free ends of the fields are now connected the speed is immensely increased, and if the ends are separated as literally it ran away. Of course there is a limit to this, and it has led to the wasting of a great deal of energy wasted in retarding the armature is not recovered, but nevertheless the increase of power due to this one economy is very astonishing.

The little motor exhibited this evening is also an efficient dynamo-electric machine. The most essential advantage which it possesses over the older forms is in the field magnets. Their peculiar shape is such that all the magnetic lines of force, including those near the neutral line, are brought into the best possible position for effecting the revolution of the magnetic armature. I believe that the distinguished inventor, Mr. Ledd, in England, claims, in an article which appeared lately in one of the journals, to have discovered the great advantage possessed by the lines of force of a nearly circular magnet over those in the usual horse shoe form magnet, but he does not appear to have applied the principle to utilise the lines of force which fill the interior of a curved magnet from the neutral to the polar points. If a bar of soft iron is pivoted at one end, so as to move in a horizontal plane, and a semi-circular magnet is placed concentrically with the circle which the bar can describe, it is found that a given force is exerted upon the bar, at a much greater distance than if a given force is exerted upon the bar, at a much greater distance than if a given force is exerted upon the bar, at a much greater distance than when the latter is within the semicircle than when it is without. I believe that no field magnets of this peculiar shape have ever been made, and herein is the secret of the power of this little motor, which weighs about 22 pounds, and which runs up to fairly with the—of the old forms of fifteen times its weight. The inductive actions which are produced in these field magnets at each revolution of the armature are exceedingly complex, and I shall not trouble further on your attention, except to give a brief resume of the practical defects of electric motors, and how they have been overcome by the investigation of which this motor is the result.

The great disadvantage of those who have used electric motors has been the battery. It gave forth offensive and poisonous fumes, it required almost constant attention, it was concentrated acids, and it became rapidly exhausted whether it was used or not.

All these objections are now done away with. The present battery is cheap, it is a strong one-fluid one, does not use concentrated acids, gives out no odour, does not require attention, is working only after the fluid has been used up by actual work, will last months or years if left to itself, and can be set in order in the briefest time. It requires absolutely no attention until the receptacle is exhausted by constant work, and it is ready without a moment's warning at all times and seasons, small though for one year. A professional seamstress would exhaust it more rapidly, but still not in a time which the exact terp places the speed of the motor under complete control without effort on the part of the operator.

The attention of mechanicians is invited to the fact that the form of motor, owing to the force being applied equally to both sides of the shaft at once, entails absolutely no wear on the journals except from the weight of the armatures so wear on the light, and from the tension of the belt, which is very small in view of the bearing is four times the diameter of the shaft, and the design of the motor is such that no strain is put upon the cross the poles of the armature and magnets to come in contact, which was a frequent source of annoyance to those in contact, the motor is attached to the machine, and is of such dimensions as to be readily concealed from view if preferred. There is also a device for readily changing the tension of the belt.

The power of the motor is sufficient to sew heavily woven linen as can be put under the presser. With twenty to two thousand stitches per minute. The speed with to the skill of the operator. A safe working speed for constant is considerably faster than is ever attained by professional sewing women, while others seldom sew more than three hundred stitches per minute.

[ELECTRO-DYNAMIC MACHINES.]

[M. McClintock says about a birth, cause he his writings. I shall not myself to do, but shall content myself with a few remarks on the statement of Mr. Kennedy's advice before spending the money, or they will probably find themselves in the position of Angles-Saxon, that "Angles" is supreme himself in the world, and that the people of the centre of the earth are "Angles" unless to reserve the middlest theories of the universe, and that he is the only Angle worthy to say "Signes." It quite accords to say "Signes" is quite wrong, but to say "Signes" is quite correct, may be just where we are then; but it is certain that the "Sol of force is the same throughout, and it is spreading in all directions, and there is but little difference in its value in the principles involved, whether it is in the form of the magnetic lines of force, or in the form of the electric lines of force, as you cannot substitute, except by actual experiment, the greatest field of force will be the strongest, we feld back the iron upon the field iron is pivoted at one end, so as to move in a horizontal plane, and a semi-circular magnet is placed concentrically with the circle which the bar can describe, it is found that a given force is exerted upon the bar, at a much greater distance when the latter is within the semicircle than when it is without. I believe that no field magnets of this peculiar shape have ever been made, and herein is the secret of the power of this little motor, which weighs about 22 pounds, and which runs up to fairly with the—of the old forms of fifteen times its weight. The inductive actions which are produced in these field magnets at each revolution of the armature are exceedingly complex, and I shall not trouble further on your attention, except to give a brief resume of the practical defects of electric motors, and how they have been overcome by the investigation of which this motor is the result.

The great disadvantage of those who have used electric motors has been the battery. It gave forth offensive and poisonous fumes, it required almost constant attention, it was concentrated acids, and it became rapidly exhausted whether it was used or not.

All these objections are now done away with. The present battery is cheap, it is a strong one-fluid one, does not use concentrated acids, gives out no odour, does not require attention, will last months or years if left to itself, and can be set in order in the briefest time. It requires absolutely no attention until the receptacle is exhausted by constant work, and it is ready without a moment's warning at all times and seasons, small though for one year. A professional seamstress would exhaust it more rapidly, but still not in a time which the exact terp places the speed of the motor under complete control without effort on the part of the operator.

The attention of mechanicians is invited to the fact that the form of motor, owing to the force being applied equally to both sides of the shaft at once, entails absolutely no wear on the journals except from the weight of the armatures so wear on the light, and from the tension of the belt, which is very small in view of the bearing is four times the diameter of the shaft, and the design of the motor is such that no strain is put upon the cross the poles of the armature and magnets to come in contact, which was a frequent source of annoyance to those in contact, the motor is attached to the machine, and is of such dimensions as to be readily concealed from view if preferred. The Scientific American.

LA BIBLIOTHÈQUE DE LA NATURE

M. G. Masson, l'éditeur du journal *la Nature*, a bien voulu nous confier la direction d'une Bibliothèque nouvelle, que nous appelons la *Bibliothèque de la Nature*, et qui, destinée à comprendre un grand nombre de volumes, sera le complément de la Revue des sciences, d'où elle tire son origine.

Dans les livraisons de *la Nature*, le lecteur suit les développements successifs de la découverte qui vient de naître, au fur et à mesure qu'ils se produisent. Nous avons pensé que les notices écrites sur un même sujet, et quelquefois séparées dans nos volumes par un espace assez considérable, pouvaient devenir le canevas de livres excellents, où les questions seraient présentées sous une forme nouvelle et avec des développements considérables, de manière à servir au spécialiste et à tous ceux qui veulent étudier particulièrement telle ou telle branche de la science. Il est d'autre part, des questions qui ne sauraient entrer dans le cadre d'un

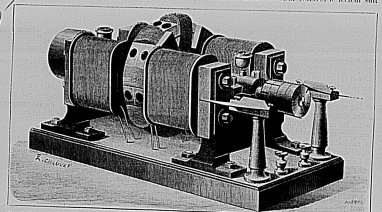

Fig. 1. Machine magnéto-électrique de M. Ruhmkorff (gravure extraite des *Principales applications de l'électricité*, par M. E. Hospitalier).

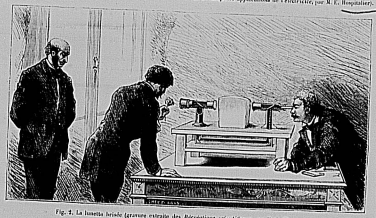

Fig. 2. La lunette brisée (gravure extraite des *Récréations scientifiques*, par M. G. Tissandier).

qui voulu que tous les jeux que nous indiquons, tous les passe-temps et les récréations dont nous donnons l'exposé, soient au contraire rigoureusement basés sur la méthode scientifique et puissent être considérés comme de véritables exercices de physique, de chimie, de mécanique ou de sciences naturelles. Il nous a semblé qu'il n'était pas bon d'enseigner à tromper, même en jouant.

La science en plein air, en plein champ, en plein soleil, est ce que nous voulons développer. Nous montrons comment on peut à la campagne, occuper et charmer ses loisirs, en observant la nature, en cherchant des insectes, en étudiant aquatiques, en observant l'atmosphère et les phénomènes célestes.

Nous enregistrons ensuite à faire un cours de physique complet sans appareil, et à étudier soi-même les différents phénomènes de la pesanteur, de la chaleur, de l'électricité et de l'électricité au moyen de simples verres à boire, de cartes, d'un bâton de cire à cacheter et de menus objets que tout le monde a sous la main. Une série d'expériences de chimie exécutées au moyen de quelques flacons de produits peu coûteux, complètent cette partie du livre établi aux sciences physiques.

Un autre genre de récréation, utile et intelligent, consiste à construire les appareils ingénieux qui composent une science. Nous donnons donc les moyens d'exécuter les appareils nécessaires, et à s'exercer à faire fonctionner ces appareils. Dans des chapitres intitulés : le Maison d'un amateur de sciences, le Laboratoire d'un amateur de sciences, nous avons réuni un certain nombre de renseignements pratiques, dont toutes les personnes ingénieuses et adroites, désireuses à se monter quelques appareils habiles, sauront à se monter quelques appareils qui permettent d'étudier ou le grand nombre des questions d'actualité ou à un grand nombre des phénomènes qui tentent de reproduire à un degré suffisant de perfection. Nous donnons ensuite, etc., jusqu'à la description de plus complexes, mais nous nous proposons d'exposer plus simples, tels que ceux qui servent à fabriquer la glace, etc.

Après avoir décrit des jeux scientifiques pour la jeunesse, nous avons voulu en indiquer d'autres pour l'âge mûr; nous avons groupé dans une seconde partie très spécial les curieux usages, si répandus aux États-Unis et en Angleterre, et si peu connus chez nous; bateaux à glace, patins, voitures à voile, courses à bicyclettes, appareils de sauvetage, etc.

Un mot que le présent ouvrage n'est pas seulement écrit pour les jeunes gens; tout le monde, nous l'espérons, trouvera quelque intérêt, quelque profit même quelque gaieté, à se mêler à notre conversation, à notre enseignement, tout en amusant les autres, à apprendre soi-même en s'amusant, tout en amusant les autres, à apprendre à tout le monde, qui est partout, sait aussi quand elle est bien comprise, procurer aux récréations et aux jeux.

Outre les gravures empruntées à *la Nature*, il y a un certain nombre d'inédites qui complètent les sujets traités, la figure ci-contre est de celle-ci; elle se trouve accompagnée, dans le livre, des lignes suivantes :

« Parmi les illusions d'optique les plus curieuses, il en est un grand nombre que l'on peut produire à l'aide de miroirs. La gravure ci-contre en est un exemple. Cet appareil, monté sur un pied fermant, permet de voir en apparence, comme le représente la gravure, un coq sortir de la bouteille et s'envoler. Le coq est en réalité placé derrière la bouteille, dans la partie inférieure. La bouteille est ouverte, et l'observateur, regardant l'image de l'objet exposé à sa droite, aperçoit nettement l'image de l'objet exposé en regard de l'objectif; cette image est reflétée par quatre lots avant d'arriver à son œil, au moyen de quatre miroirs disposés dans l'instrument. Le pied se ferme et est fermé de toutes parts et l'illusion est complète. »

Nous ajouterons que la Bibliothèque de la Nature s'accroît d'année en année, nous promettant un grand nombre de nouveautés, de nouveaux volumes de cuisine, d'ameublement, de mécanique, etc., et nous espérons que bon nombre de nos lecteurs, de plus en plus nombreux, voudront bien contribuer à ces ouvrages, destinés à répandre le goût de l'étude et l'amour du travail, du travail qu'ils font et ne cessé de faire à la publication qui en est la source.

GASTON TISSANDIER.

LE GRISOLMÈTRE ÉLECTRIQUE

La *Nature* a donné, dans le numéro du 5 mars 1877, la description d'un appareil inventé par M. Coquillon, et qui permet, au moyen d'un dosage calorimétrique assez simple, de déterminer la proportion de grisou contenue dans l'atmosphère des galeries de mines. Le grisoumètre de M. Coquillon est aujourd'hui entre les mains de tous les ingénieurs, et il a donné des résultats très satisfaisants.

Cependant, il présente l'inconvénient d'exiger l'emploi d'une galerie de mines, ou tout au moins d'une atmosphère confinée, pour opérer. Or, il est souvent très important de connaître, sur un point donné, la proportion de grisou contenue dans l'atmosphère d'une galerie de mines. Le grisoumètre de M. Coquillon ne peut donner que des résultats approximatifs, et il est d'ailleurs très délicat à manier. Il est donc très désirable d'avoir un appareil qui permette de déterminer avec exactitude la proportion de grisou contenue dans l'atmosphère d'une galerie de mines, et qui puisse être manié par des personnes peu habituées à faire des expériences de physique.

Le grisoumètre électrique de M. Le Chatelier, dont nous allons donner la description, paraît répondre à ces conditions. Il est fondé sur ce fait, que la vitesse de propagation d'une explosion dans un mélange gazeux est d'autant plus grande que le mélange est plus explosif. Si donc on détermine la vitesse de propagation d'une explosion dans un mélange d'air et de grisou, on pourra, en comparant cette vitesse à celle qui a été déterminée dans des mélanges d'air et de grisou de titres connus, déterminer le titre du mélange gazeux dans lequel on a opéré.

Pour mesurer la vitesse de propagation d'une explosion, on emploie un fil métallique très fin, qui traverse le mélange gazeux dans lequel on veut produire l'explosion. Ce fil est parcouru par un courant électrique, et il est rompu par l'explosion elle-même. Si l'explosion se propage avec une vitesse déterminée, elle rompra le fil au bout d'un temps déterminé, et si on connaît la longueur du fil, on connaîtra la vitesse de propagation de l'explosion.

Pour mesurer le temps qui s'écoule entre le moment où le courant est lancé dans le fil et celui où il est rompu par l'explosion, on emploie un appareil très simple, qui est représenté dans la figure ci-contre. Il se compose d'un électro-aimant, dont l'armature est maintenue par un ressort à boudin. Cette armature porte un levier, qui, lorsque l'électro-aimant est excité, est attiré par lui, et vient frapper contre un timbre. Le courant qui excite l'électro-aimant est lancé dans le fil métallique qui traverse le mélange explosif, et il est rompu par l'explosion elle-même. Le levier est alors ramené par le ressort à boudin, et il vient frapper contre un second timbre. Le temps qui s'écoule entre le moment où le courant est lancé dans le fil et celui où il est rompu par l'explosion est donc mesuré par l'intervalle qui sépare les deux coups de timbre.

Pour mesurer cet intervalle, on emploie un chronographe, qui est représenté dans la figure ci-contre. Il se compose d'un cylindre, qui est mis en mouvement par un mouvement d'horlogerie, et qui tourne avec une vitesse connue. Sur ce cylindre, on fixe une feuille de papier, et on trace sur cette feuille, au moyen d'un crayon, une ligne droite, pendant que le cylindre tourne. Cette ligne droite est interrompue par des dents, dont le nombre est connu, et qui sont produites par le passage d'un ressort, qui est mis en mouvement par l'électro-aimant. Lorsque le courant est lancé dans le fil métallique, l'électro-aimant attire son armature, et le ressort qui est fixé à cette armature vient frapper contre le cylindre. Lorsque le courant est rompu par l'explosion, l'électro-aimant cesse d'agir, et le ressort revient frapper contre le cylindre. Il y a donc deux dents sur la ligne droite, et l'intervalle qui les sépare correspond au temps qui s'est écoulé entre le moment où le courant a été lancé dans le fil et celui où il a été rompu par l'explosion.

Pour mesurer cet intervalle, on emploie un chronographe, qui est représenté dans la figure ci-contre. Il se compose d'un cylindre, qui est mis en mouvement par un mouvement d'horlogerie, et qui tourne avec une vitesse connue. HEINRICHS' DYNAMO MACHINE AND ELECTRIC LAMP.

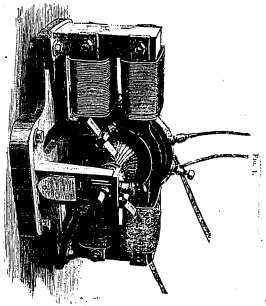
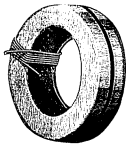
A GLANCE down the lists issued by the Patent Office will show that inventors are by no means satisfied with the dynamo-machines at present in use, excellent though they may be, and some of the more recent devices having undergone a preliminary trial are about to enter into competition with the Gramme, the Siemens, the Brush, and the Siemens. Amongst these is the machine invented by Mr. Heinrichs of which we give illustrations, and which has already been exhibited at work in the shops of Messrs. Perrin and Andrew, Deptford, South-London. It is rather remarkable that the most successful dynamo-machines in existence are all based on the principle of the annular armature first discovered by Dr. Antonio Pacinotti of Florence, Italy, and that of Mr. Heinrichs is no exception. By using a chamelled ring armature, however, a form suggested by the theory he has worked out, he has, it is believed, avoided all the disadvantages of the other ring forms, has utilised the greatest possible length of the insulated conducting wire for the generation of current. The result is that M. Heinrichs obtains from his lights from a machine little if anything larger than the single-light generators with which the public are now familiar. In Fig. 1, we have a perspective of the machine (one-eighth the full size); but the difference in construction will not be apparent from that. In Fig. 2, a cross section, the channelled ring armature is clearly seen. The channelled ring core

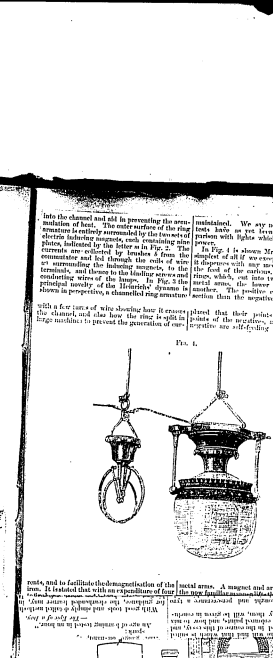


is made out of a bundle of thick iron wire formed upon a metal casing p. Around the core c is wound the insulated conducting wire w in 36 sections. These overlie the outer surface of the core entirely, and by crossing the channel of the core the inner leaves of the latter, when becoming magnetised, have no influences whatever upon that very short and nearly useless portion of the conducting wire which crosses the channel. The 36 sections are connected with each other consecutively by 36 commutator plates c^1 c^2, in a

Fig. 3.



manner similar to that adopted by Pacinotti. On the shaft s is a boss b, with six sets of spokes and held securely by metal bolsters. Wire coils which rest upon the spokes, but are cast into the channel and aid in preventing the accumulation of heat. The outer surface of the ring armature is entirely surrounded by the twenty-six electric fostering magnets, each containing nine plates, indicated by the letter a in Fig. 2. The currents are collected by brushes b from the commutator and led through the coils of wire on surrounding the fostering magnets, to the terminals, and thence to the positive screws and conducting wires of the lamps. In Fig. 3 the principal novelty of the Heinrichs' dynamo is shown in perspective, a channelled ring armature with a few turns of wire showing how it crosses the channel, and also how the ring is split in large sections to prevent the generation of cur-



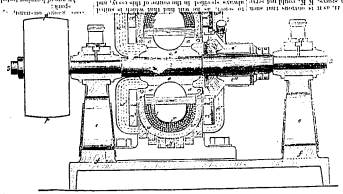
rents, and to facilitate the demagnetisation of the iron. It is stated that with an expenditure of four

maintained. We say nominally, because the tests have as yet been made only by comparison with lights which are sold to have that power.

In Fig. 4 is shown Mr. Heinrichs' lamp, the simplest of all if we except the Jablochkoff, for it dispenses with any mechanism for regulating the feed of the carbons. These are made in rings, which, cut into two pieces, are held by metal arms, the lower points touching one another. The positive carbons are of larger section than the negative carbons, and are so placed that their points are just above the points of the negatives, so that both positive and negative are self-feeding by the weight of the

Fig. 4.

sucial arms. A magnet and armature applied in the way familiar to many will be found to



the whole arrangement, prevents all shadow. It will be really understood that this lamp is not only the simplest yet invented, but the carbons being in the annular form, occupy less room for a given length than the straight ones. There are no wheels, chains, or racks, liable to get out of order, the feeding arrangement being simply the action of gravity. Some little difficulty has hitherto been found in getting suitable carbons made, but Mr. Heinrichs has devised an ingenious die which will enable a pressure of 100 tons to be brought to bear, and under that compression the circular carbons will no doubt be equal to the best of the ordinary form. As exhibited, the machine was supplying three lights which, as we have mentioned above, were of the nominal power of 2,000 candles.

whom a claim was being brought for 38,000*l*. He advised voluntary liquidation, and moved a resolution to that effect, which, after considerable discussion, was agreed to. The chairman stated that there was a proposal to form a new organization, which would be brought forward at the proper time. A committee of five gentlemen to co-operate with a similar number appointed by the creditors was agreed to, who should confer with the liquidator as to the course to be adopted. It was decided that Mr. Watchouse should be liquidator, conjointly with Mr. W. S. Peat, of Middlesborough.

THE ELECTRIC LIGHT.

SECOND ARTICLE.

(SPECIAL.)

THE SIEMENS SYSTEM.

THE principal electric lighting system of this country is that of Messrs. Siemens Brothers, Charlton. It has been introduced on an extended scale to light the promenade of Blackpool, a watering-place in Lancashire, and the Albert Docks, London, while its successful introduction into the great Reading-room of the British Museum, the *Telegraph* steamer, and elsewhere has brought it into note for lighting ships and buildings. It is also about to compete with other systems in illuminating the London Bridge district of the City, and the result of the trial will be awaited with interest.

In the Siemens system there are two classes of machines and lamps; one class designed for producing powerful single lights, and another for producing several lights of less power, all fed by the same current, and distributed so as to form a uniform illumination over a considerable area. The first are serviceable for the head lights of locomotives or steamships, for lighthouses and torpedo-work, while the latter are useful for street, hall, and factory lighting.

The dynamo-electric machines of the first class generate continuous currents. Assuming the current to exist in a coil or rather series of coils, of wire revolving in the magnetic space or "field" between the poles of very strong electro-magnets.

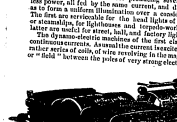


Fig. 1.

These coils are wound on an iron cylinder, mounted on an axle, carrying the driving-pulley, which holds the running belt from the engine or motor supplying the moving power. In the dynamo machine the axle is wound across the iron cylinder as the coil, but in the Siemens it is wound on Gramme-fashion round the cylinder, which here also serves for the coils a horizontal one. Sixteen machines with both of this construction, two on a table, enclosing the revolving coil or armature is that the pins of wire cross to the poles magnets, "at right angles, thereby getting the full effect of their power to excite a current. Each opposite pair of electro-magnets consists of a set of iron bars placed side by side, to form a kind of plate, and curved in the middle, as shown, to make room for the revolving coil.

These bars are wound at their flat parts with insulated wire, in such a way as to produce a strong magnetic pole at the middle or arched portion of the bars when a current is sent through the wire. In this way two opposite magnetic poles are formed, one above and one under the revolving coil, in which a current, or rather series of currents, is generated as it revolves past the poles. The series of currents follow each other so rapidly as to merge into a continuous current, and they are tapped from the coil by a double pair of straight copper combs, rubbing across the ends of the wire on the cylinder as it revolves.

In first starting the machine the current obtained is weak, and owes its existence to the "residual" magnetism or traces of magnetism left in the poles of the electro-magnets from the last time of use. But this weak current is allowed to flow through the wires of these electro-magnets in order to strengthen them when a powerful current is obtained from the revolving coil. A very short time suffices for this process, and the current can then be used for lighting purposes, as well as keeping up the strength of the electro-magnets.

Messrs. Siemens manufacture six different sizes of these machines, some of which are made with their magnets placed vertical instead of being laid horizontal as in fig. 1, D, the largest size, is capable of yielding an "arc" light of 12,000 candles, and requires about 7-horse power. It is 42 inches long by 31 inches wide, and 24 inches high; weighs about 19 cwt., and costs 175*l*. D² machine yields a light of 2,000 candles, and requires 2½-horse power. It is 29 inches long by 23 inches wide, and 19 inches high; it weighs 2 cwt. 3 qrs., and costs 80*l*. D³, the smallest size, yields a light of 200 candles, and absorbs about ½-horse power. It is 21 inches long by 11 inches wide, and 18 inches high; weighs about 1 cwt. 1 qr., and costs 32*l*. These machines can, of course, also be used for producing incandescent as well as "arc" lights, but in this case the yield of illuminating power would be considerably less than the above estimates, as it would be if more than one lamp were placed in the circuit of the current.

For several lamps in circuit, that is, for "dividing" the electric light, the most economical machine is that rendering up alternate currents. Fig. 3 represents the "Siemens" alternating current machine. It consists of two circular iron frames, bored with an even number of electro-magnets, or "bobbins," placed face to face, but separated by a narrow space in which revolves a number of coils of copper wire. In these coils the alternating currents are generated by their revolutions between the poles of the magnets. The latter are excited or made magnetic by the continuous current from a small machine of the continuous-current type for exciting. The alternating currents thus produced are led away by metal cords and conducting wires to the lamps, from about forty to forty of which may be placed in the same circuit, according to the power of the machine, and each giving a light of 20 candles or 100 candles. Four different sizes of this machine are made: W, the largest, giving from 20 to 40 lights, measures 37 inches by 37 inches across about the horse power, and costs 175*l*, or, with its exciter, 225*l*.; W, the smallest size, measures 19 inches by 17 inches high, and costs 50*l*.

Fig. 2.

The lamp used with the first or continuous current type of machine is illustrated in fig. 2. In it the lower carbon-holder is a fixture, and the upper carbon-holder is in the form of a rack, which, in sinking down under its own weight, turns a pinion or toothed wheel. In order to moderate the speed at which the rack descends, or, in other words, the feed of the upper carbon to the arc, a common clockwork escapement-wheel with its pendulum is fixed on the same axle with the pinion gearing with the rack. This escapement, which can be lifted up by the electric current (on solenoid or spiral of wire, attracting an iron core) connected to the frame. During the ordinary burning of the lamp a small lever fixed to the movable frame catches the upper carbon-holder at a standstill; but when the arc becomes too large, or the current is otherwise weakened, the attract the iron core strongly enough, and therefore lets the frame drop a certain distance, when the free end of the little lever is arrested by a projection of the lamp-casing.

Fig. 3.

and the pendulum is free to move. The upper carbon at once begins to descend, but as soon as the distance between the two carbons is diminished the strength of current increases, the solenoid again lifts the frame, and the lever again stops the descent of the upper carbon.

When it is desired to keep the arc of light in precisely the same position or "focus" the lower carbon is encircled by a copper ring, through which it is pressed upward, in order as it wastes away, by means of weights or a spring. These, according to sort, burn from 6 to 10 or 10 hours continuously without change of carbons, and they range in price from 16*l*. to 25*l*. When fitted with alarum regulator and time-keeping hole the price ranges up to 26*l*. The hanging-pendulum lamp (non-focusing), shown in figure 2, costs 12*l*.

It will be readily seen that, owing to the way the strength of current regulates the distance between the carbons in these lamps, that they ought not to be more than one lamp in circuit, for two lamps would interfere with the regulation of each other's light. The lamp of Messrs. Siemens, intended for burning along with others in the same circuit, or, in other words, for use with the alternating-current machine (fig. 3), is shown in fig. 4. It differs from the lamp just described in having coil of wire instead of one, and the frame carries two cores actuated by the solenoid. The added solenoid serves as a shunt, or by-path, to the current, and forms a high-resistance or main solenoid and the carbons, while part flows through the high-resistance. One solenoid tends to move the movable frame in one direction, while the other tends to move it in the other, and as its ordinary position depends on the *resistance* in solenoids, not the strength of current, any variation in their resistance causes the frame to move, and with it the upper carbon, until the normal resistance has been re-established.

Fig. 4.

These lamps cost somewhat less than the others, the pendent form shown above being quite low priced. It is enclosed in an opal globe, 20 inches in diameter, and carries an inverted umbrella reflector, 4 feet in diameter, to shed down the light upon the space below.

(To be continued.)

Electrician
Mch. 19 1881

THE CONSERVATION OF ENERGY.—In the *Proceedings of the American Academy of Arts and Sciences*, vol. xv., part 2, 1879-80, Mr. John Trowbridge illustrates the conservation of energy as follows:—Let an induction coil be set in action. In the circuit of the secondary coil place another coil of fine wire. Adjust the terminals of the induction coil so that the spark just passes, then place a core of iron or a bundle of iron wire in the coil which has been included in the secondary circuit. The spark instantly ceases to jump. A portion of the energy of the current in the secondary circuit has been consumed in magnetizing and demagnetizing the iron introduced into the additional coil. The work done in this way is capable of being measured. It is also evident that, when a number of telephones are in the same circuit, a part of the energy of the human voice is consumed at each telephone in heating the magnetic cores. In the same paper Mr. Trowbridge alludes to his researches as to how much of the work employed in driving dynamo-electric machines is consumed in heating the iron cores of the generator of electrical currents, and whether this loss of work should turn our attention to forms of generators in which this loss is obviated.

IRON.

THE FARCOT DYNAMOMETER.

It is highly important to be able to measure the power absorbed by a machine, especially for determining the horse-power of the motor intended to drive it and the strength of material required for the transmitting gear. Notwithstanding the many appliances invented for this purpose, almost the only one in general use depends upon a style which traces the varying strains on a band of paper moving at a uniform speed; but this machine possesses the great disadvantage of not enabling an immediate indication of the power that is being absorbed, and of rendering necessary much subsequent calculation, so that considerable time must elapse before the desired result is arrived at. M. E. D. Farcot, mechanical engineer, of Paris, has lately turned his attention to the improvement of pressure and exhaust fink. In testing them with an ordinary dynamometer, he was so struck with the evidently erroneous results obtained, that he set to work to devise a trustworthy instrument from which a reading might be taken at any moment. The principle of his dynamometer consists in measuring, by weighing, the strain transmitted by the leading side of a belt passing over the pulleys of two shafts, the driving and the driven, with the intervention of tension pulleys hung on swing beams.

In the opposite engravings, fig. 1 shows a perspective view, and fig. 2 a diagram, of the Farcot dynamometer, while figs. 3 and 4 are end and side elevations respectively. The frames, AA, are provided with bearings in which revolve the two shafts, *a* and *d*. On the former is keyed the pulley, D, driven by a belt from any motor; and on the latter the pulley, D, driven. Independent of the shafts are the pulleys E and *f*, connected by the belt, C, which also passes over the two tension pulleys, *e'* and *f'*, revolving loose on their axes, *b* and *c* respectively, in the swing frames, whose points of suspension are *e* and *f*. From the points B and H, equidistant from the centres, are suspended equal weights, *β* and *β'*, just sufficient to prevent the belt from slipping. It is between the power and the resistance, and may be regarded as the measure of the latter, and may be readily found. When the belts C and C' are subjected to the dynamometer set in motion, without, for the present, being connected with anything, the pressure of the tension pulleys on the belt C, due to the weights adjusted, is counterbalanced, and weights must be added to the plate until it is restored. This is the "tare," which must be deducted from the total weight on making an experiment; but practically it is found more convenient to construct a table of "tares" for different velocities. The dynamometer is now connected by a belt with the machine to be tested, when the equilibrium is again destroyed; and more weights must be added until it is again restored. The doubling of the belt, in passing over the tension pulleys, is exactly compensated by the latter being hung

midway in the swing frames, so that the weight on the plate multiplied by the circumferential velocity of the driven pulley gives the work or resistance in kilogrammetres or foot-pounds, as the case may be. The speed at the circumference of the driven pulley, *e'*, or revolution indicator, *l*, connected by a strap with the pulley, *f*, on the driven shaft, *d*. As the machine is arranged in the diagram, it is true that, for very exact results, there is a slight correction to be made for the angle formed by the belt, *c*, with the vertical, but a constant is readily found to meet the case. Each revolution of the driven pulley corresponds to 1·57 metre, which, at the rate of 10 revolutions a second, gives a speed of 15 min. 7 sec.; therefore each kilogramme added to the weight plate represents a work of 157 kilogrammetres, or, rather, 150 with the correction. So sensitive is the apparatus, that the motor must be provided with a heavy fly-wheel, or each stroke is manifested by a vibration of the swing-frames; and it is a curious fact that a mere drop of oil given to the bearings is equal to about a pound removed from the weight plate. Provision is K, carrying a Salter's balance, *g*, and a small grooved pulley, *h*. A cord with weight, *β'*, at the end, passes from the balance round the grooved pulley, *h*, on the driven shaft, and over the small pulley, *h'*, thus constituting a Prony brake.

Some experiments made with a dynamometer on this system having a driven pulley 80 centimetres (2·3 inches) in diameter, were made on a 120 centimetre (5·9 inches) Farcot pressure fan, with a blast orifice of 24 centimetres (9 inches), with the following result. With a speed of 500 revolutions per minute of the fan and 181 of the dynamometer, the pressure was equal to 12 centimetres (4·9 inches of water, with a volume of 6·198 cubic metres (219 cubic feet). With 530 revolutions per minute of the fan and 166 of the dynamometer, the pressure was equal to 16 centimetres (5·9 inches) of water, with a volume of 5·987 cubic metres (205 cubic feet). M. Farcot's new fan, as he terms it, permits of their being calculated in a more simple manner than usual, by taking, as the basis the speed corresponding to the pressure desired, and providing a chamber reduced to the minimum of the sectional area necessary to give the volume required at the given pressure. The "turbine," or revolving portion, differs from others in the curvature of the blades, thus increasing the centrifugal force, because the air, instead of following the radius, escapes in the direction of a line more inclined than the radius itself. The result is that the air circulates through the turbine in the smallest possible time, so as to cause a minimum of friction and, therefore, of vibration. The air thus moves with a uniform speed equal to that of the turbine. The "fly-wheel" of air, arranged around the turbine between two cheeks, plays a large part in preventing the vibrations and rendering the delivery uniform. The annular chamber is arranged spirally so as to assist all the useful effect. This arrangement permits light substances from reaching corn and other matters to be conveyed with a single fan, When a cone cannot conveniently be added to obtain a progressive exit and increase the arrangement of double suction ventilator; but in this case the speed must be greater.

(81, *a*) It will be perceived that there is given a difference of only one line between the Front-Pitch and the Concave-Parallel Pitches. The really correct addition, for Concavity, is a Board of such Compass as the present, is 2 lines; but the 1 line is more perfectly because among other reasons, given with *Double* Front-Pitch, as the exact area of the Concave Pitch Board is—for the sake of uniformity—adopted also for the Flat-Front Pitch. Which double obligation, when a short-front is preferred, it is usually out of question to have the said Cutting made wider than the Pedal-Frame is at the front glove—for otherwise an unsightly gap will be visible after the Pedal-board has been pushed back into its place. In all instruments, therefore, which possess a complete Fronted Plinth, the Checks of a *Sunken* Pedal-board (whether Concave or not) will never extend beyond the distance already given. (If there be *Composition Pedals* under the provision for the Bearings of which the chief object of this elongation of the Cheeks is to secure a sufficient length of Bearing for the Pedal-Key, whenever the Pedal-board is a *Detachable*, a *Falling*, or a *Sliding* one.) In some instruments the entire Pedal-Frame itself may have to enter the Plinth one inch (see Head of Post, in Report, of Front-fronts), but the resultant gap of no small a dimension is to be of practical service.

2. It is now necessary to consider the Concave Pitch of the Manual with the Pedal-board. Hitherto it is has been assumed that both Manual and Pedal Keys are Flat—that is, that the Front, respects right and left, of the Case, and yet a Board of the Clavier be allowed to Concavity, is not so in fact, for it has been found that the Pedal-board of such Concave Pitch is not always by any means that a given Pedal Key must always be set—exactly with the corresponding Key beneath a Manual Key,—whatever be the Compass of either the latter Pedal-board or the Manual.

3. This matter also is fully gone into under the head of Point in Report of Front-boards. It will be sufficient to say here that the Point of Centre for Concavity always set at the exact right and left Centre of the Manual Board, and that with a Pedal-board either the CC or the C-sharp Pedal Key (preferably the latter) will be found to be directly beneath the Middle C of the Manual.

4. In order to add to the utmost the correct Sufficiency of the Pedal-board, the Front of the Keys, for Concavity, from the Front of the Case as a whole—here considered—is to be set back to the Front of the Pedal-board, and the consequent slight discrepancies will have to be met by the Pedal-Frame, or Pedal-Fronts, upon which shall exist between the Front Projections of the Plinth. The Manual is in all cases assumed to be made to Normal Scale (see Report of Manuals).

5. With the Position and Scale of the Pedalboard as already understood and—and with the Concave Pitch of the Keys of Board adopted, the dedications of the Pedal Clavier will be as follows:—

If, With the Pedals placed C under C, and the Manual extending from CC to F' (Two Oct. and a Fourth), the Pedal-board will be (in. for *Low Set*). This will manifestly ensure that the space between the Plinth-Projections be extended to Sixteen Inches (in. as a gap of 2in. will appear on the *right* of the Pedal-Frame.

If, The Pedal-board C be added to the top of the Manual, the latter, and of course the Pedals and the left Front-Projection of the Plinth with it, will be driven one half of a Manual-Natural Key-distance still *further* to the left; and this will necessarily involve the setting of the *right*-hand Plinth-Projection at a half of such Key-distance to the *right*. Thus the dimension of 2in.—full note that—to be added to the dimension, making the clear length-distance between the Plinth-Projections to be 17in.—full more than is required for the actual entry of the Pedal-Frame, and involving a gap of the said 2in.—full at the right hand of the said Frame.

If, If the Pedals be placed C sharp under C, the left-hand Plinth-Projection will obviously be driven 11in. yet more to the left; and the right-hand Projection must consequently be set the same amount to the right. Thus there is then involved an addition of 22in. to either of the two previously given dimensions for C under C.

I. With the Scale of the Pedals set as already understood in Report, and their Clavier made to extend the full amount of Two Oct. and a Fourth (C to F'.—Vide Report of the Board below, remember, still *Essential*—the dedications of the Clavier will be as follows:—

II. With the Pedals placed C sharp under C, and the Manual reaching from CC to F' (Two Oct. and a Fifth), the Pedal-board will be 23in. full for far to the *right* than given at page 50—full at the *left* of the Pedal-Frame.

(*To be continued.*)

THE DEVELOPMENT OF THE PACINOTTI RING.

IN our last number we had the pleasure of bringing before our readers Heinrichs' new dynamo-magnet generator, in which he employs the now classical Pacinotti armature, and, as we said on that occasion, it is rather remarkable that the most successful dynamo machines at present in use are all based on the principle of the annular armature first applied by the Abbé Pacinotti, of Florence, in 1860, which was first described in *Il Nuovo Cimento*, which can be seen at the British Museum Library. We shall now, in this article, show the most important forms of ring armatures in use, and also Mr. Heinrichs' theory of the generation of electric current in a ring armature. This theory differs from others in very important respects, in his always been understood that the soft iron ring-core, when in action, acquires a magnetic polarity dependent on the electric action of the core, but Mr. Heinrichs shows that when the coil-wire and the inducing magnets fields, the ring-core, when in action, will acquire hardly any magnetism, and electric currents are generated in the insulated conducting wire surrounding the core by the influence of the inducing magnets only; and when the inducing magnets are removed, the ring-core will not retain any magnetism, it will acquire on the inner surface a reversed magnetic polarity to the outer surface.

In the former case (the small ring), the entire conducting wire surrounding the outer surface of the ring will be useless for the production of currents, while in the latter case the inner reversed magnetic polarity will give an impulse to the generation of currents in the insulated conducting wires surrounding the inner surface of the ring-core in an opposite direction to the current generated on the outer surface of the ring-core, as we shall see later on.

We shall show now, firstly, how currents are generated on a bar-magnet and on a ring-magnet. It is well known that when a piece of soft iron is brought with one of its ends close to a magnet (Fig. 1) this piece of soft iron will

Fig. 1.

become also a magnet, and the one end nearest to the magnet acquires south polarity and the other end south polarity. In the middle of the piece of soft iron a neutral line, *t t*, will be established, and if the piece of soft iron were surrounded with insulated conducting-wire, a current would be set up or generated in the entire length of the wire in *one direction*. As is well known, this is the principle on which all so-called magneto-electric currents are generated. If now we change the inducing magnet to the

A NEW CONTINUOUS CURRENT DYNAMO-ELECTRIC MACHINE.

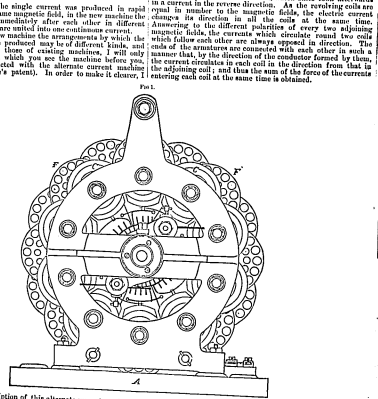
By F. von Hefner-Alteneck. (Translated from *Elect. Zeit.*)

The growing importance of the supply of electric currents by means of machinery, induces me to direct your attention to a new dynamo-electric machine, by means of which the combination of a single induction current with continuous action is brought about in a manner different from that of any former machines.

Whilst in these the single current was produced in rapid sequence from the same magnetic field, in the new machine the currents produced immediately after each other in different parts of the machine are united into one continuous current.

Although in the new machine the arrangements by which the separate currents are produced may be of different kinds, and may be copied from those of existing machines, I will only describe the form in which you see the machine before you, in which it is connected with the alternate current machine (Siemens and Halske's patent). In order to make it clearer, I

Fig. 1.



must give a short description of this alternate current machine, although I have already done so on a former occasion.

Fig. 3 shows a part of the cross section of the machine, and Fig. 1 will at the same time refer to Fig. 2, although this is a longitudinal section of the new continuous current machine.

On the base plate A, Fig. 2, are fixed two iron supports B, B, of the form of which is shown by the drawing. On the inner side of each of these supports are fixed an equal number of electromagnets, C, C, the poles of which, facing each other, are spread out into suitably shaped plates, N.S., N.S. The polarity of these electro-magnets is so managed that each one has the opposite polarity of the one facing it, and of those on the same side right and left of it.

From this arrangement it results that the pole plates of the pairs of electro-magnets opposite to each other form powerful magnetic fields, of which each has the opposite polarity to the plate next to it.

Through the magnetic fields runs induction coils which have a wooden core, and are connected with the axle A, filling up as far as possible the space between the magnetic fields. For the sake of distinctness, only two of these coils are shown in Fig. 3, and these with half of the coil a.

is between the point next to it. Thus, in the one half of the coil an upward current is induced, and a downward one in the other half, which currents mutually strengthen each other. When the coil is between the two magnetic fields there arise induced currents in the two halves of the coil, which unite soon afterwards in a current in the reverse direction. As the revolving coils are equal in number to the magnetic fields, the electric current changes its direction in all the coils at the same time. Answering to the different polarities of every two adjoining magnetic fields, the currents which circulate round two coils which follow each other are always opposed in direction. The ends of the armatures are connected with each other in such a manner that, by the direction of the conductor formed by them, the current circulates in each coil in the direction from that in the adjoining coil; and thus the sum of the force of the currents entering each coil at the same time is obtained.

In Figs. 4 and 5, for the sake of clearness, the coils introduced into the circuit are distinguished to the eye, those in which the current flows in one direction being coloured black, while those in which its course is opposite are left white. The alternate polarity of the magnetic fields is shown in the same way. For the same reason, the coils and the magnetic fields are shown concentrically to each other, the diagram only representing with accuracy their relative angular position. With reference to these illustrations, the following must also be borne in mind. Each white coil which approaches a white magnetic field, and each black coil approaching a black one, develops a current in the preceding a black field, or vice versâ, on the contrary, develops a current whose motion is opposed to that of the machine. To put it more simply, coils approaching fields of the same colour induce the opposite colour, they induce a current in the reverse direction. It will be seen from Fig. 4 that at the moment of the revolution which it represents, the coils are approaching magnetic fields of the same colour, whilst in the eighth of a revolution more the reverse will be the case. Hence, in consequence of their [illegible] to my preceding [illegible] coils is united to produce a [illegible], while, by the continued revolution

THE ELECTRIC EXHIBITION.

THE CLAIMS OF GRAMME AND PACINOTTI.

A LETTER FROM PROFESSOR CARHOLL ON THE RIVAL CLAIMS TO THE INVENTION OF THE DYNAMO-GENERATOR—TESTIMONY OF PROFESSOR WHEATSTONE—DESCRIPTION OF THE TWO MACHINES.

To the Editor of the Tribune.

SIR: In my correspondence with you on the Electric Exhibition, I had made mention of the little machine on view in the Italian Department, known as the Pacinotti dynamo-generator. Its presence at the Exhibition has excited general interest and discussion from the fact that it seems to prefigure a later invention, the Gramme armature, which has carried magneto-electricity from its former state of an experimental science into the ranks of the practical arts. At the suggestion of friends I was induced to suppress the paragraph, as likely to lead to unfair conclusions respecting the merits of the later inventor, M. Gramme. At the same suggestion I beg to refer to your indulgence a brief summary of the main points in the discussion:

Up to about 1860 the machine now known as the dynamo-electric generator had not advanced beyond the point of perfection of the old "Alliance" machines, in which a series of spools of wire, enfolding each its separate core of soft iron, were set around the rim of a circular disc, and by its revolution brought into rapidly successive contact with the poles of the so called field magnets. In this form of armature the cores, it will be observed, were perpendicular to the plane of the wheel, while the wire coils, naturally, were wrapped parallel to this plane. In 1860 Professor Pacinotti, of Pisa, invented a new armature, first officially made known some years after. In this form the soft iron core is continuous, a bar of solid metal bent into a ring, and wrapped at intervals with spools or bobbins of wire in folds perpendicular to the plane of motion, and so presented to the magnetic poles in a position at right angles with that of the old machines. Scientists recognized in this new form a marked advance in magneto-electric science; the machine was examined, discussed, used for experiment, and finally—as I am rightly informed—relegated to the shelves of the physical cabinet, if not actually dismounted.

Some years later, M. Gramme, then a plain, thoughtful, practical mechanician in Paris, ruffled of all knowledge of Italian or Italian scientific reports, struck out his own form of magneto-electric wired, which under the name of the Gramme armature is now known to all enlightened countries, and lies at the bottom of all present devices for producing magneto electricity. His armature presents striking features of resemblance with the Pacinotti, in the essential idea, while it combines elements of mechanical detail which immensely increase its effect, and render it practically available for commercial production. His continuous circular core is itself a bundle of wires, not a solid bar, and his enveloping wire coil is continuous, not broken into separate sections. Instead of two extremities of a horseshoe bar magnet, he surrounds his armature the same reason, the coils and the magnetic fields are shown concentrically to each other, the diagram only representing with accuracy their relative angular position. With reference to these illustrations, the following must also be borne in mind. Each white coil which approaches a white magnetic field, and each black coil approaching a black one, develops a current in the preceding a black field, or vice versâ, on the contrary, develops a current whose motion is opposed to that of the machine. To put it more simply, coils approaching fields of the same colour induce the opposite colour, they induce a current in the reverse direction. It will be seen from Fig. 4 that at the moment of the revolution which it represents, the coils are approaching magnetic fields of the same colour, whilst in the eighth of a revolution more the reverse will be the case. Hence, in consequence of their [illegible] to my preceding [illegible] coils is united to produce a [illegible], while, by the continued revolution

N.Y. Tribune, Sept. 23rd, 1881.

On the 17th of July 1871, Professor Zenobi Pacinotti [illegible] from the French Academy of Sciences the description of a machine invented by M. Gramme." On the 25th of August, 1871, Professor Fabrizio Meucci wrote a letter to the Secretaries Perpetual of the French Academy to [illegible] the same date in 1860 he had constructed for [illegible] a machine which in the theory of Pixii, an electro-magnetic machine based on the same principle as the Gramme machine. But neither Professor Pacinotti nor Professor Meucci claimed for M. Gramme more than a merit of invention, on the contrary, enforce the correctness of the claims of the above-named patents.

I am sorry that the short time since to send you a complete report, but what I have pointed out will be sufficient for your purpose.

The Journal Encouragement de Paris decreed to M. Gramme a gold medal of the value of 3,000 francs; *La Chambre des Deputes* voted an extraordinary prize of 50,000 francs for M. Gramme, the great prize of 50,000 francs was awarded to Professor Pacinotti, Gramme and Meucci created Chevalier of the Legion of Honour, and of the Order of Leopold. All these honors and prizes, it seems, have been conferred upon him, but his merits [illegible] to an original one. I remain, dear sir, yours faithfully,

WARMINGTON.

To Professor Carholl, Paris.

On the morning of my departure from Paris, September 1, I had a brief interview with M. Gramme himself at the house of its confidential adviser, M. Hippolyte Fontaine. The points were substantially in effect such as I have stated. M. Fontaine urged, with especial emphasis the following heads: In purely theoretic regards, the Pacinotti wheel supplies, it is conceded, the idea; the scientific germ of the Gramme armature. But the Pacinotti machine was a modest little bit of apparatus (about the size of an ordinary kitchen coffee-mill), was never used for the production of electric force, on the modern commercial footing, and could not have done so even if got up on the most large and elaborate scale. It never passed from the stage of experimental to the practical stage. M. Gramme, on the other hand, with no inkling of the Pacinotti idea, struck out his own invention, on independent lines, and promptly developed it in its present point of surprising commercial electricity, as parlance, to all the various departments of human utility in which it is now employed.

I then presented the unselfishness of views which I had myself claimed in my own account in urging more positively the claims of Professor Pacinotti to have not wrested the palmies of your readers. It is barely possible that this communication may be of interest to persons scientifically interested in science, as well as to that large class in liberal and practical life who look to the fruits of science and practical invention, especially in one which bears so powerfully on human progress and importance as the art of magneto-electricity. Very respectfully yours,

CHARLES CARHOLL.

New-York University, Sept. 24, 1881.

N.Y. Tribune, Sept. 23rd, 1881.

THE GRAMME DYNAMO.

To the Editor of the Tribune.

SIR: In your paper of to-day I noticed a peculiar error in Professor Carroll's letter on Gramme machine, and though I am not by profession a scientist, I have a number of electrical machines under observation, including this particular machine, and would therefore request you to allow me to correct the mistake. It is stated that "... His (Gramme's) armature spools." This is not correct; for, on the contrary, Gramme's and Pacinotti's armatures are alike in the very particular. Gramme's armature is composed of a series of strips of metal, very thin and [illegible] being placed longitudinally along the whole of the [illegible]. These strips are separated by similar strips of [illegible] and the whole mass is connected with the beginning [illegible] which is a peculiar feature of Professor Carroll's [illegible] Pacinotti's armature is composed of a solid iron ring, [illegible] Professor Carroll will now either do me [illegible] in the electric machines, or in the Marcelle "La [illegible] Electricite" or "Les Merveilles de la Science" [illegible] he will find descriptions and accurate drawings of these particulars.

NEW-YORK, Sept. 24, 1881. G. DAVIS.

beginning as cold, dry winds, they grow more thirsty as they grow warmer, and enquire in intense desperation over. They drink up the waters of the Caspian, the Sea of Aral, and the salt lakes of Asia, and also of the coast of Mediterranean. They have blighted and blasted Mesopotamia and Persia, and turned what was once a paradise into an arid waste. In conclusion, the speaker argued that the climate enjoyed by the ancient Assyrians must have been an insular climate like that of the modern British, and ended with a well-drawn parallel between the national characters of the two races.

NEW ELECTRIC MOTOR.*

By WILLIAM WOODCUTT GIBSON.

An electric motor, as the name indicates, is an engine for converting electricity into mechanical force. This is done in an efficient manner through the medium of electro-magnetism, and the honor of inaugurating the movement which has led to the utilization of this force, as a motive power, is due to no less a person than Professor Henry. His first paper on this subject appeared in 1831. In the following year Sebrandus du Moncel constructed his motor and described it in detail. These early electric motors were rude machines, about as efficient as a locomotive steam engine, but it hardly took the world long to perfect the one from a required economy to equal that of the other. But Negro's motor consisted of a fixed electro-magnet, which, by uniform interruptions of the electric current, alternately attracted and released a lever by which the mechanism was driven.

In 1835, Prof. Jacobi, of St. Petersburg, constructed an electric engine at the expense of the Czar Nicholas, with which, after four years of further experiment, he was able to drive a rowboat-load test against the swift current of the Neva at the rate of three miles an hour. His enormous battery consisted of sixty-four cells, containing every square feet of platinum.

This was in all respects an apparent failure, and the philosopher was thoroughly disheartened while standing upon the threshold of a brilliant success. In the first place, he attempted the impossible in trying to get a great power economically from any battery, and in the second place no powerful battery had yet been invented. But his failure was an excellent one, and the subsequent inventors failed to equal it until Gramme, of Paris, discovered that one of his own dynamo-electric generators would act in the reverse direction as an admirable motor.

The interval between 1838, when Jacobi's motor was abandoned, and 1870, when Gramme's machines came into notice, was occupied by a large number of inventors, who brought to their work a world of ingenuity, and all the learning of all the centuries save one, but that one was the only key to success—*the magnetic induction*. In the meanwhile Mr. Sturgeon, a former worker after the nineteenth century philosopher's stone, dashed the hopes of his co-inventors by his demonstration of the economy of force. This magnificent work, like the grand-el perhaps in the help of science, was immediately made the basis of a series of experiments, which it would be out of place to detail here. Suffice that Mr. Joule proved that the best results of all scientific minds that the mechanical energy of the electrical current, produced by the consumption of one pound of zinc in a Daniell's cell, is sufficient to raise 1,100,100 pounds raised to the height of one foot; in a Grove cell, which has one and three-quarter times the electro-motive force of Daniell's, to 1,925,0 0 pounds raised to the height of one foot, or, in the simple chromic acid battery used before you, which has double the electro-motive force of a Daniell's, 2,222,200 pounds raised to the height of one foot. Dr. Scoresby and Mr. Joule state their conclusions in the following sentence: "Upon the whole we feel ourselves justified in fixing the maximum available duty of an electro-magnetic engine, worked by a Daniell's battery, at 400 pounds, raised one foot high for each grain of zinc consumed." This is about half the theoretical duty. In a Grove battery the same proportion would give 741 pounds, and in the chromic-acid battery 800 pounds, raised one foot high for each grain of zinc consumed. This result was immediately compared with the duty of the best type of steam engine per grain of coal, and it was found that one grain of coal lifted 142 pounds one foot high. At that time, the most favorable computation, costs ten times as much as coal, and the force it yields is, therefore, as 142 is to 80 or about nine times as costly.

The conclusion instantly drawn by the scientific world was that electricity produced by the consumption of zinc can never compete with steam, but it is the purpose of this paper to collect certain facts which will show that this conclusion is erroneous.

History is teeming with instances where noted scientific men declared that there was nothing attainable beyond their immediate vision, and greeted with sarcastic epigrams and brilliant sophistry the proposition to accomplish results which were impossible. So it was of old in the steamship. An eminent scholar and mathematician proved by the most unanswerable arguments the paradoxicalness of a steam boat. A steamship was an absurd dream. His calculations showed that one could not be built large enough to carry her coal across the Atlantic. And so these gentlemen, having proved that electricity produced by zinc is many times more costly a source of power as steam produced by coal, predict that electric motors can never usefully compete with steam engines. Now, mon power, according to the tables of a well-known English engineer, is one hundred times as costly as steam; nevertheless there are several circumstances in which we prefer men. It is evident that we would never employ men if we could get a steam engine to do the work more economically, and it is equally certain that we would not use electricity when steam is applicable. But steam is not applicable, for reasons which will appear as we proceed, to work in which we require a small amount of power for a constant confidence for action. In these cases—such as barbers' lathes, dental engines, and sometimes also in small machine shops, which employ but a small force of men—we have never been able to find a source of power united to the work which, if not as cheap in proportion as the steam engines, should yet be more economical than human energy. The fact is that whereas, according to the, the best electric motors are also times as costly as power, human energy is eleven times as costly as that of steam. Now, as human energy, which is one hundred times as costly as steam, is completely perfected to small duties *in fortiori* electricity will, when developed to the same perfection, find it employment to almost any extent. The energy thus saved from extinction in the exercise of these can be elevated to a higher use.

Any of illustration, the application of human energy

* Paper read before the Franklin Institute, Nov. 17, 1880.

to the sewing machine is not only a false economy, but has proved the cause of many new and painful diseases in female operators, which combine their force and effect the physique of their offspring. If any motor can be substituted for human energy in this field, there can be no greater or more far-reaching consideration offered to invite attention to it.

The sewing machine is in almost every home, and the evils of these diseases are spread in every class of society. The remedy, as before mentioned, is a household motor, and it was natural to suggest a small steam engine for this purpose; but steam is unsuited to this end, because

First,—It requires time and trouble to start it to work and a busy housekeeper, who may only need, perhaps, to do five minutes of sewing, has no time to waste.

Second.—It is dangerous, liable to explode, or to burn out the boiler, or get various portions of its complex mechanism out of order, so as to require an experienced engine driver to repair it.

Third.—It emits an offensive odor of burnt or boiling oil, and vitiates the atmosphere with the products of combustion.

Fourth.—It is really much more expensive than those steam engines from which our calculations were made, for gas is consumed for a household engine, the fuel amounts to from two-fire to twenty-five feet of gas per hour, according for a motor giving one-thirty-third of a horse power, as much as the fuel of a six or twelve horse-power steam engine.

This last consideration would not weigh with the actual sufferers of the acute forms of disease, but the other objections are serious, and apply to all heat motors, such as gas, steam, and caloric engines.

Other motors are before the public—the various hydraulic motors which require the special introduction of water pipes and waste pipe, and entail yearly visits from those friends of humanity, the plumber and the tax collector. Then there is the spring motor, which you wind up every quarter of an hour or so, expending, of course, much more power in the winding than you get out of it in work, and which has the unhappy habit of breaking its hands accidentally and venting its store of energy where it is least needed. Then there is the curious chair motor, whose mechanism is connected with the seat of the chair, and by various levers, cranks, cams, and wheels is to save shaking nerves. The seat of the chair gradually sinks about three inches beneath the weight of the operator, driving the sewing machine the meanwhile. The operator then rises, the spring lifts the seat, and the performance is renewed. A rapid speed can be obtained by rising and sinking forty times per minute.

The only motors which seem to be available for this purpose are electric motors, used with batteries. They may be divided into two classes, which utilize the same attractive force of an armature to an electro-magnet like the motor which drives your sewing machine, in the ordinary literary upstairs, and those which utilize the attraction and repulsion of two or more electro-magnets.

The former are by intermittent attraction only, and are wasteful of electric energy, because the useful magnetism, at the moment of the cessation of the current, retards the passage of the armature away from the pole which has attracted it.

Those of the latter type, however, convert a portion of the wasted influence of the residual magnetism into a useful force. In fact, all dynamo-electric generators, when used as motors, convert all magnetic resistance to motion into a counter electro-motive force.

Strange to consider a counter force as a help, but in point of fact it retards the consumption of power in that it very and tends to depolarize the zinc plates. It has been usual to regard this counter electro-motive force as a disadvantage. A small number of the type before you was laid motionless while a sufficiently powerful current—let us say of four webers per second—observed its cells. A running galvanometer was in circuit, whose deflection was carefully observed. Then, without changing the connections, the motor was allowed to run at full speed, when the galvanometer indicated a considerable drop in the strength of the current. The electro-motive force of the battery was practically constant, electricity obeying the law that formula

$$\text{Electro-motive force} = \text{Current} \times \text{Resistance}$$

the galvanometer should have indicated the same current as at first, unless the resistance has been changed or a counter electro-motive force produced. The speed of rotation was then diminished by a brake, and the needle immediately indicated a stronger current. This is in direct conformity with the well known fact that the electro-motive force of a dynamo-electric machine varies with the speed of rotation, whereas the resistance of a coil is not affected by mere motion.

A still more striking proof that the "back-pull" of residual magnetism may be converted usefully into a motive force is exemplified in a motor constructed some time ago by the writer on the same principle as this one, save that the coils were fixed and connected with the battery. The current of the battery is sent through the armature, which revolves with considerable rapidity. If the fresh coils of the field coils are now connected the speed is immensely increased, and if the coils are separated a spark appears, of course there is some loss. The entire amount of energy consumed by the motor is, however, less than when the coils are disconnected

A NEW DYNAMO-ELECTRIC MACHINE.

We give an engraving of a new continuous-current dynamo-electric machine, recently perfected by Mr. Clinton M. Ball, of Troy, N.Y. This inventor has been engaged during some years past in building machines similar in type to the alternating-current machine of Hefner-Alteneck (recently described in the SCIENTIFIC AMERICAN SUPPLEMENT), especially in respect to the shape therein of solid metal parts in the armature, the latter being constituted in the form of a disk composed of a series of coils without iron cores, arranged and adapted to be moved in a magnetic field consisting of a series of poles of alternately opposite polarity on the same side of the disk, and facing opposite sides of the disk.

Mr. Ball has perfected several forms of continuous-current machines of this general type, and from among them we have selected two forms, which we illustrate. These machines have been operated with entire success at Troy; and samples of the machine are either already installed at the Paris Exhibition of Electricity, or are on their way to that destination, forming a part of the joint exhibit made by the "White House Mills" and Mr. Ball.

The bipolar machine, Fig. 1, reproduces the effects of the well-known Gramme machine, over which it possesses important advantages. Its special peculiarities and advantages may be briefly summed up as follows: The armature is composed of coils, six in number, each of which occupies a sector of the disk of 60°. These coils are made self-supporting in the disk, without iron cores or metallic parts other than the wire of which they are composed, and are connected in a continuous circuit. The commutator plates are six in number and constitute the terminals of offshoots from the junctions between two contiguous coils. These commutator plates are zonally disposed apically about the axis of the arbor of the machine so as to show at opposite ends an angular displacement from axial parallelism of 90°. From this it results that during rotation a pair of diametrically opposite coils in the armature are by circuited during one twelfth of a revolution at the neutral point of the machine, and this effect recurs successively through the entire series of coils. It will be understood that an important advantage is gained by this arrangement, inasmuch as the resistance of the inactive coils of the armature is thereby eliminated from the internal circuit of the machine. This machine, used as a generator, presents striking and powerful effects with small expenditure of power. It may be used as a very perfect form of an electro-magnet motor. It runs without serious sparking at the commutator, and is simple and compact in construction. A further noticeable feature, which exists furthermore in all machines of this type, is the absence of any noticeable external magnetic field when running.

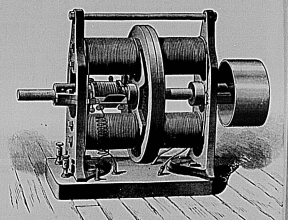

Fig. 1.—BIPOLAR DYNAMO-ELECTRIC MACHINE.

The other machine, Fig. 2, is a compound multipolar continuous-current machine embodying characteristics of fundamental arrangement which distinguish it from all others, while, as before stated, in some of its theoretical aspects it resembles the machine of Hefner-Alteneck described in the article in the SUPPLEMENT.

The machine represented in the engraving, it will be noticed, has only six opposite pairs of poles in the field system. The continuous current armature system of the machine has eight elements, and the commutator twenty-four plates. The armature is otherwise composed in two sections or layers, the major section of which is utilized through a commutator or contact rings of ordinary construction for doing work upon the external circuit, while the continuous-current section maintains the magnetism of the field.

In this machine, developed and constructed long before the publication of any descriptions of Hefner-Alteneck's machine, the currents are commutated continuously, somewhat as in his machine, the commutator connections being so made that, while the contact brushes remain in a fixed position, the currents are brought in them from the consequent electrical poles of the armature—the consequent poles, during rotation, assuming successively different positions in relation to the field, and completing the cycle of changes during half of a revolution of the armature. During this time, furthermore, the line bisecting the armature and marking the consequent electrical points, has twice traveled over the complete circuit of the field in advance of rotation. In the case of a machine having more poles in the field than armature elements, the movement of this line would be retrograde; however, if the multiple of half the number of field poles into the number of armature elements remained the same, the number of changes would be the same in either case.

It will be seen that this machine differs from that of Hefner-Alteneck in respect to the proportion of armature elements to the number of poles of the magnetic field—the Ball machine, having a larger number of armature elements than of field poles, while his has a less number. The arrangement selected by Mr. Ball is more favorable to a simplification of details of construction without detriment to the efficiency of the machine.

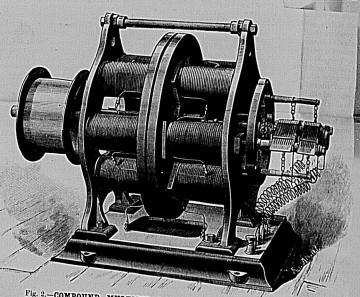

Fig. 2.—COMPOUND MULTIPOLAR CONTINUOUS-CURRENT MACHINE.

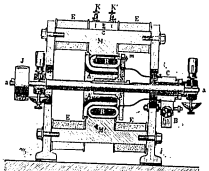
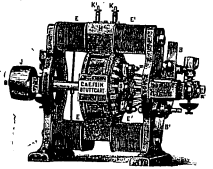
At a speed of rotation of 950 to 1,050 per minute, and with an expenditure of 5½ to 6 horse power, this machine has proved capable of maintaining a series of ten to twelve lights of good power. The machine weighs only 670 lb.

FEIN'S DYNAMO ELECTRIC MACHINE.

Last year Mr. W. E. Fein patented in Germany the machine we illustrate below. We are indebted to the inventor for the description we are now able to give. Dynamo-electric machines constructed upon the Pacinotti-Gramme principle have this disadvantage, that the inducing force of the poles of the electro-magnets acts only upon the external windings of the wire of the armature, the other parts being far less affected by the inductive action, thus increasing the resistance of the circuit, and conducing to the heating of the ring.



To avoid these drawbacks flat rings instead of cylindrical ones have been used, so that the exciting force can act on both sides of the ring, but the windings of such a ring diverging radially necessitate a much greater diameter in order to use a certain length of wire, and this enlargement of the circumference, increasing as it does the resistance to rotation, requires a great er expenditure of motive power for a flat than for a cylindrical ring.



Considering these circumstances, Mr. Fein designed the following construction, by which he claims to preserve the cylindrical ring, and to obtain the advantage it gives without the disadvantages. He says:—"By fixing it in a particular manner to the axle, and by giving the armature a suitable shape I arranged for the exposure of nearly the whole length of the coils to the effects of the magnets.

"Fig. 1. shows the cross section, Fig. 11. a side view of this new dynamo-electrical machine. The cylindrical ring R R, furnished with the coils, is screwed on to the brass star S S, which by means of a socket is keyed to the axle A A', put in motion by the pulley J. The ends of the single coils pass partly through insulated apertures in the spokes of the star, partly through the internals between the same to the commutator G, which, in order to be easily accessible, is placed on the axle lengthened for this purpose outside the framing.

"By means of the two brushes B B, sliding on the commutator, the currents are collected in the usual manner.

"To avoid the Foucauld-currents and the production of heat resulting therefrom, the ring itself is composed of a large number of insulated iron-foils. The cores of the electro-magnets are furnished with the armatures M M', which are placed in front of the external circumference of the ring; in connection with these are the half-round shaped pole pieces A A, which surround the ring on two more sides, so that nearly the whole length of the wire moves in the magnetic field, leaving only those few parts of the wire which are opposite the brass star unaffected by the inducing force. The increased useful effect of this machine may be shown in a simple and surprising manner by taking off the pole pieces AA, the induction thus affecting only the windings on the outer circumference of the ring, as is the case with the Gramme machines; only half of the force of current is obtained which the machine furnishes when under the influence of the armatures AA. The advantages of my construction may be summed up in the following points:—

"1. The windings of the coils of the ring are exposed nearly to the whole of their length to the influence of the magnets, diminishing thus the resistance of those parts which have no electromotive force.

"2. The composition of the ring is such as to restrict as much as possible the generation of Foucauld currents; therefore, the loss of motive power by the production of heat is rendered insignificant, and the excessive heating of the ring prevented.

"3. The ring being of a proportionally smaller diameter the velocity of its rotation may be increased, and the machine requires less motive power in proportion to its efficiciousness."

MR. HERRING'S UNIVERSAL ALPHABET.

The following is a copy of a portion of a letter addressed by Mr. Herring to the Right Hon. Sir Stafford Northcote on the subject of the adoption of his instrument by the Post Office:—

"I will not suppose that it was intentional on the part of Sir Richard Cross, but the tactics adopted have been absolutely disastrous to the petition itself, as the fact of my having petitioned the Sovereign by the advice and with the approval of the Secretary of State deprives me of the privilege of bringing it before the House of Commons. This Sir Richard Cross distinctly wrote to Mr. Goschen, who would otherwise have moved in the matter. Thus a conspicuous case, bristling with every form of deception and injustice, fully detailed in the petition has been allowed and assisted by the Conservative party to pass unheeded, the present Postmaster-General,

RICHARD HERRING

Mr. Fawcett, being content to write to me that 'he does not feel called upon to enter into the past history of the case.' Thus, also, all my money and time expended at the suggestion of the telegraph authorities have been wasted, all their agreements with me being unfulfilled, the eminent scientific men engaged and paid by me to act as referees at the request of the Post Office not being even invited to meet, and the telegraph service, as many competent persons believe, has been deprived of a much more simple, speedy, and accurate system than the one in use. Eminent electricians affirm that had my system been adopted it would have rendered the Post Office independent of the serious risks of the present crisis.

"No doubt you are acquainted with the present system of telegraphing, and, therefore, I need only explain what I

and water. Ericsson states: "There is a rainless region extending from the northwestern coast of Africa to Mongolia, 9,000 miles in length, and nearly 1,000 miles wide. Besides the North African deserts, this region includes the southern coast of the Mediterranean, east of the Gulf of Cabes, Upper Egypt, the eastern and part of the western coast of Syria, part of Syria, the eastern part of the Red Sea, Eastern Arabia, the greater part of Persia, the extreme western part of China, Thibet, and lastly, Mongolia. In the western hemisphere, Lower California, the table-land of Mexico and Guatemala, and the west coast of South America, for a distance of more than 3,000 miles, suffer from continuous rainless heat." To utilize this great energy Ericsson is mainly devoting his remaining years.

Studying the movements of birds and fishes, Ericsson became convinced that the principle of rapid motion was in oblique action, and the final fruit of this belief was the screw propeller. Although there has been much dispute regarding this invention, the honor of its introduction and practical utilization is undoubtedly due to him. In 1839 his propeller, the Francis B. Ogden, towed the British Admiralty barge on the Thames. His vessel was eighty feet in length and forty feet beam, three feet draught and was furnished with two screws, each five feet three inches in diameter. This pretty demonstration of its power failed to convince the Admiralty, and resulted in Ericsson's leaving England for America in 1837. Through the efforts of Captain Robert F. Stockton, of the United States Navy, who had ordered two vessels similar to the Ogden, and after a delay of two years, the authorities at Washington gave Ericsson an order to build a trial boat, and in 1844 the Princeton was completed. The lamentable disaster caused by the bursting of the great gun, the "Peacemaker," on the Princeton at the time of its public exhibition is too well known to need a description here.

The revolution in naval engineering caused by the little Monitor in Hampton Roads is well known; the incident forms one of the most important events during the last war. Sweden, Norway and Russia immediately adopted the plan of the Monitor for its war vessels, but England failed to grasp the idea until the appearance of the double turreted vessel—Miantonomoh—in English waters in 1866.

Captain Ericsson, having introduced a new system of naval architecture, is now devoting a por-

DYNAMIC GENERATORS.

According to reports attributed to the officers of the Western Union Telegraph Company, where dynamic generators have been substituted for decomposition batteries for the generation of the current, the cost of charging the wires with the dynamic current is about one-half what it was under the old system. Readers of the PRESS will recall that some months ago, in a description of a system of telegraphy devised by one of our prominent electricians, in which the dynamic current was employed in place of that generated by decomposition, the reduction in the cost of charging was stated in figures closely corresponding to those developed by the experience of the Western Union Company. The statement was sharply taken up at the time by the partisans of the dynamic current in a series of communications, and some even went so far as to claim that the actual use, not for sell, of dynamic electricity was about one-sixtieth of that developed by decomposition. This extraordinary assertion was based upon the fact that a pound of coal contains a certain amount of power whose quantity in foot-pounds can be accurately computed and determined. The amount of power in a pound of copper or zinc is also accurately ascertainable; and when these two factors of the problem alone are compared, and this comparison is made the basis of an estimate of cost, the relative ratio shows an advantage in favor of coal of between 25 and 60 to 1. The reasoning looked very plausible on paper, but, unfortunately, there were certain factors which the partisans of dynamo-electricity did not take into account. In the use of the dynamic generator the number of foot-pounds of energy contained in a pound of coal is one thing, and the actual percentage of that energy which appears in the circuit as electricity is quite another. In the first place, the imperfect combustion of the coal in the furnace must be regarded, and, although it may seem strange to the popular reader, in view of the great advances that science has made of late years, it is none the less a fact that not far from four-fifths of all the heat-forming energy contained in a pound of coal is wasted in the furnace through imperfect combustion; so that in operating a steam engine only about one-fifth of the actual energy of the fuel is converted into steam. The fact is so well verified that able engineers have already turned their attention to the construction of furnaces in which perfect combustion, and the next step in the economical generation of power will no doubt take the direction of better constructed furnaces. In the second place, only about 40 per centum of the energy transferred from the engine to the generator is actually converted into available current, and a three-fifths of the steam power is lost before the transformation into current is completed. If, for example, the amount of energy contained in a pound of coal be placed at 100, 80 of this 100 will be lost by imperfect combustion, and 12 out of the remaining 20 will be unutilized in the development of heat in the generator. The result is that only 8 per centum of the actual energy contained in a pound of coal is transformed into current in the use of the dynamic generator, while the larger proportion of the energy contained in the copper or zinc is converted, and this is the reason why the theoretical and the practical relations of the two methods are so at variance with each other, and why those who based their computations upon a mere comparison of foot-pounds of energy were so wide of the mark in their statements.—*N. Y. Times.*

ELECTRIC MOTORS POSSIBLE.

Siemens, the German inventor, who has constructed a railway in Berlin upon which the propelling power is an electric motor, has been starring for some time past in this city, making his head-quarters in the Windsor Hotel. He became intimate with Jay Gould, Russell Sage, and Cyrus W. Field soon after his arrival in this country, and the latter gentleman accompanied him to Europe, adopting his electric motor upon the elevated railroads here. A few days ago, in company with the three gentlemen named, he made a trip to Irvington over the railroad. Mr. Dolph, Commissioner of Streets Department, and President Sullivan, of the Manhattan Elevated Railroad Company, were also of the party. All three said that it was perfectly satisfactory in effect to say that it was probable that the result of that experiment would be a complete success. Mr. Siemens himself was not present, but was satisfied in a letter to Mr. Sage, "moved to talk in a three-cornered position between his knees and his chin," according

ENGLISH MECHANIC AND WORLD OF SCIENCE: No. 882.
Feb. 17, 1882.

Attention is drawn by a writer in *Cosmos Repertorium* to a small dynamo-electric machine, driven by hand, and meant for laboratory or lecture use. It is supplied by Krattlinger, in Vienna. The *Spyanne* is fixed between the divergent legs of a solid table, under the top of which is a steel axle for the driving-wheel, which gives rapid motion to the Gramme armature through an endless band. The terminals are brought up to binding screws near a handy switch-board at the top. Of various experiments that may be made with the machine, the following are some:—A Bernier incandescent lamp (also supplied by Krattlinger) gives an intense light, sufficient for capital projections with Böhler's Stéréoscope. A thin platinum wire, about 20in. long, can be coiled while hot. The inductor of a bipolar Gramme machine with steel magnets, from which the iron wound wheel has been removed, can be set in rapid rotation by means of the Krattlinger machine, illustrating the transmission of force by electricity.

Electrical Progress in Vienna.

An exhibition of electricity and its various uses, after the plan of the late Paris Exhibition, will be held in Vienna during the coming summer, under the management of Count Wilczeck and Baron Victor Ebenspurr. It will be held in the central building of the International Exhibition of 1873.

The Telephone Exchange, opened in Vienna in December last, is said to be doing well. By the middle of February there were three hundred subscribers, and connections were being made with two hundred more. The charge is 100 florins, or about £10, a year.

A very successful trial has just been made of the Brush system of electric lighting in Vienna. The Place of St. Stephen and the neighboring streets were lighted with four-teen lamps, with such excellent results that preparations are making for the electric illumination of the famous Ringstrasse, the finest avenue in the city if not in Europe. One hundred and thirty Brush lights will be required. The light will also be introduced into public and private buildings.

THE ENGINEERING AND MINING JOURNAL.
Nov. 12, 1881.]

The Force of the Future.—Dr. C. W. Siemens, in a recent lecture, says: One of the great practical illustrations furnished by the Paris Exposition has reference to the transmission of power from one place to another by means of the electric conductor. The electric railway leading from the Palace de la Concorde into the exhibition and only half a kilometer in length, does its work regularly and well, running a trip every five minutes, and conveying generally as many passengers as can be packed into the cable and outside of a train-car of ordinary dimensions. This apparent propulsion will soon be in operation on a new line of railroad, six miles long, with which I am connected, in the north of Ireland, to be extended, if successful, to a further coal distance. This will give us twelve miles of electric railway without expenditure of fuel; for the motive power will be obtained from a neighboring water-fall which at present runs to waste. Mr. W. A. Traill, the resident engineer of the line, has already commenced operations, and I hope that by next spring visitors to the sister island may reach one of the most interesting agency. The experience gained by my brother in the working of the first electric railroad, two miles in length, established by him at Lichtenfelde, near Berlin, leaves no reasonable doubt regarding the economy and efficiency of this mode of propulsion, although it is not anticipated that it will supersede locomotive power upon our main trunk railroads. It will have plenty of scope in relieving the tailing horses on our tramways, Metropolitan Railroads, where the collection of the products of combustion causes not only the propulsion but the suffocation of passengers.

AN ELECTRIC POWER METER.

At a recent meeting of the Physical Society, Mr. C. Vernon Boys exhibited and described a very ingenious new integrating-machine of his invention, and its application as a measurer of the electric energy in the circuit of an electric lamp or a dynamo-machine. Mr. Boys's mechanical integrator belongs to the class termed tangential, in which motion essentially of a small disc or wheel results through the surface of a drum or cylinder. When the wheel is driven parallel to the drum parallel to the axis, there is no motion of the latter; but when the wheel is inclined to the axis the drum rotates, and in this way it can be used to find the work done by a fluid pressure reciprocating engine, or the work done by a current. The effect, as both form one part of a factory in another. Mr. Boys has constructed, on this principle, a motor-meter energy meter which integrates the product of the strength of current and the difference of potential between two points with respect to time. In the current is passed through a pair of concentric solenoids or coils of wire, and in the annular space between these is hung a third solenoid, the upper half of which is wound in the opposite direction to the lower half. By the use of what Mr. Boys calls "a solenoid of the second order" the magnetic force is confined to a small portion of the suspended solenoid, and by this means the attraction between the fixed solenoids upon it is disproportional of position. The middle solenoid is hung from the end of a long torsion-rod (torsion is retarded by a counterweighted wheel), which attains of regulating the meter to give the required indications for any particular lamp. The motion of the clock gives standard time. The motion of the rod is caused to indicate the integrating wheel, and this wheel rests on a cylinder given the energy required. The cylinder is driven by means of an indicator or diagram, as the case may be. The wheel is driven in equal number of turns in opposite directions to the axis of the cylinder, and it is under this instrument insensible to external magnetic force.

Phila. Press, Aug 9.83.

Electricity Flying the Thames.

From the St. James Gazette.

A trial was made on the Thames on Tuesday of boat propulsion by electricity, a run being made from the Crystal Palace to Chelsea and back, a party of twenty-two to see a "Torrens" launched. The boat, forty feet long, is fourteen and three-feet straight of water when loaded. The motive power is one Gramme with eighty Sellon-Volkmar batteries of the large variety of sixty pounds each, or, in all, two tons, stowed beneath the floor. The screw is eighteen inches in diameter, with three feet of pitch, making 350 revolutions per minute. The speed obtained on the voyage was over seven miles per hour against the tide down the river, immediately after the turn of high water, being at the rate of thirty-seven minutes. For river pleasure purposes such a boat has many advantages over steamboats, for the machinery and engine occupy the least part of the vessel. The steering, reversing and manipulation of the boat were very quick and effective. The vessel is intended for the Vienna Exhibition, which will open next month, and where she deserves to create considerable interest.

Resistance of Dynamo Machines.

To the Editor of the Scientific American:

Some time ago Mr. Weston and I had a discussion in your columns regarding the proper resistance of dynamo machines. Mr. Weston then claimed that low resistance machines were wrong in principle and impractical. Mr. Edison, on the contrary, claimed in the practice that a low resistance machine was the best form. His experiments have now resulted in a practical machine, which is running in London, having a resistance of one two-thousandth of an ohm. On this resistance he is able to convert 125 horse power of energy into electricity with a minimum loss, and to avail himself of 97 per cent of the electricity outside of the machine.

Electricity as a Motive Power.

THE development of electricity as a motive power is an which, though difficult of realization is yet strongly to be desired. Its convenience is not, however, so very far off, if we may take the appearance of the streets of Dublin as indicating the subject as conclusive evidence of their probabilities of the future. For instance, Mr. Hemmins, presiding last week at a meeting of the Dublin Society of Electrical Engineers, observed that the ardent who needs a little motive power for his work, is forced to seek it in the employer's factory, while the thousands of workmen and workwomen there were and their bodies and destroy their strength in impelling the sewing machine, the lathe, and the other motive powers of small industry. The division of electric energy is destined to effect an entire revolution in this sphere. The day will come, and sooner than the coming, when the artisan family will see over their dwelling by means of a magic wire the force which is now so costly to them, and this will be the demonstration that he is the benefit of the working class. The solution of the question of motive force for small industrial industries is by this apparently not far distant, and it is curious to contemplate the change in our social and public arrangements which such a development of the electric motor would accomplish. At an inference, meaning apart for small machines of every kind could be readily obtained and cheaply purchased, what a revolution would come over the existing labor system! How many workmen now and workwomen for women would be closed, the sweating-system employes being supplied in their homes with the means of carrying on their work in their own apartments. Without attempting to foreshadow all that might happen, certain it is that the cost of driving lathes and machines of every kind would be largely diminished, and the means and motive for extending their application supplied. From all points of view it is much to be wished that this novel mode of actuating machinery may be developed so that its efficiency and economy may establish a reputation, and be largely patronized by both large and small employers of labor.—*Building and Engineering Times.*

Inventor Jan. 19, 1883. 58

NEW METHOD OF GENERATING ELECTRICITY.—A discovery how to generate electricity by the act of combustion has been made by Dr. Bunsel, of La Rochelle. This discovery, which is yet only in its infancy, will probably lead to many developments. Dr. Bunsel has an electro-generative herb or candle, which yields a current of electricity by the act of burning. It is prepared by making a paste of coal-dust and molasses, and moulding it into a stick, which serves as the positive pole of a candle. This rod is then covered with asbestos in a thin sheet, and dipped into fused nitrate of potash until a good thick coating of the nitrate adheres. The wick being ignited, it burns away, and a current of electricity is drawn from the candle by wires inserted into the nitrate and the coal. The light which this current is comparatively feeble and lost to part of such practical value, the discovery is important as showing the possibility of such a generation. It is pointed out that the candle has lost a fraction so constructed that on burning any solitary fact in it so as to give heat, it would, at the same time, keep up an electric current sufficient to ring electric bells or charge an accumulator, and thus give light also. Dr. Bunsel is understood to have this also in view, and his researches are based on the discovery of Becquerel, the great French physicist, who found that red-hot carbon plunged into nitrate of potash forms an electric battery.

Inventor Sept. 21, 1883.

THE TRANSMISSION OF POWER.—M. Bertrand, perpetual secretary, has announced to the French Academy of Sciences the complete victory of M. Marcel Deprez, inventor for transmitting electrical force to great distances. Theoretical objections were raised on the occasion of the recent experiments at the Northern Railway station. Certain improvements in the mechanism have since been made, and now Colonel Laussedat, of the engineers, at the head of a scientific government committee, certifies that a vertical of 14 kilometres from Grenelle was by M. Deprez's apparatus emulated to work to the extent of 7 horse-power a small mill, a printing press, and other machinery at Grenelle.

ELECTRIC LAUNCHES.—An electrical launch was tried on September 10, by Messrs. Gilbert, Bagle & Co., Glasgow, on the Clyde, at Kilmarnock. It was driven by Clark's patent battery and engine, Mr. Clark, the patentee, himself managing the machinery and also steering the boat. The only other persons on board were Mr. Bagle and Major Mcclliver, of Bristol and London, for whose benefit the trip was made. Clark's patent dispenses with dynamo machines and accumulators, and need no charging, and enables the motive to be instantly re-filling the batteries with a simple chemical compound. In the launch boats a speed of four to five miles is obtainable, and Major Mcclliver, who had with him a 16-foot launch, built for him by Powell & Douglas, of Waukegan, Illinois, has ordered it to be fitted with Clark's machinery. If the experiment be successful, Messrs. Bagle are to construct a much larger vessel for him, which it is intended to take through the canal between the Rhine and the Danube next year, to make the trip from the German Ocean to the Black Sea through these rivers and their artificial junctions. The large boat will be designed for a speed of ten miles an hour, and it will take several months to construct her, but the smaller one will probably be on the Thames before the end of October. Major Mcclliver believes that he can make the trip from ocean to ocean in about three weeks, and intends to do so without any assistance whatever.

THE COLWELL MOTOR.

An Invention for Which Great Things Are Claimed.

Steam Supplemented, but Not Quite Supplanted.

A Combination of Most Ingenious Devices.

Lynn, like its lone for some months past there have been references, especially in the Lowell papers, to a new and wonderful motor, which would be revolutionary in its effects, and Lowell business men have become largely interested in its financial as well as mechanical aspects. Rev. Dr. T. St. Colwell, pastor of the First Baptist Church in that city, is a brother of the inventor, and associated with him in the development of his ideas. The inventor, William S. Colwell of Pinehurst, Pa., was for 19 years a manufacturer of steam engines, but has devoted the past six years entirely to the "triple thermic motor." It has been patented throughout the civilized world. One motor has been set in operation at Pinehurst, where it operates a saw mill. Another is now in operation in New York, where it was exhibited. It is said by some one who occupies nearly a page in the Lowell Courier-Journal to be

"A Mechanical Marvel."

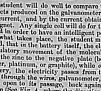
Carbon, when in use as a combustible element of steam boilers, instead of its vapor of water. The bituminous coals of certain localities of one part of carbon and two of ashbor, and is produced by heating coal, which is burned in a superheated atmosphere, with the natural atmosphere excluded. It has been used heretofore for extracting oil from seeds and dissolving gum and other material for rubber goods. Its chemical symbol is CH, and of 100 parts it contains 92.3 parts of carbon and 7.7 parts of hydrogen. Naphthaline was discovered 50 years ago by Laurelles. Its practice it requires 350 pounds of sulphur and 350 pounds of wood charcoal to produce 870 pounds of bi-sulphide of carbon. Many years ago it was found that a mixture of carbon and vapor of sulphur, and is produced by passing vapor of sulphur over red hot charcoal, in closed cylinders. Its a gaseous

of the best is borne by the rollers. The castings holding the rollers are constructed with a step resting on the desk, and the centres arranged in such manner that when the bars or handles are pulled over to the full extent, they cannot be thrown back by a weight on the rollers.

THE DYNAMO: HOW MADE AND HOW USED.—III.*

By Sidney H. Bowden.

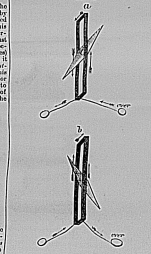
IT THE student will do well to compare the effects produced on the galvanometer by the battery current, and by the current obtained from the magnet. Any simple coil will do for this purpose; and in order to have an intelligent perception of what takes place, the student must bear in mind, that in the battery itself, the electricity causing the movement of the needle is passed from the zinc to the negative plate (be it copper, silver, platinum, or graphite), while outside the battery it is the electricity passes from the latter round through the galvanometer, or other circuit, open or closed, back again to the zinc plate (See Fig. 4, where the section is the conductor, or "current," is shown by the



arrows; the plate marked Z being zinc, the one marked C being carbon, copper, or other current electrode). If the positive pole (the one from which the "current" is flowing; the wire attached to the C plate) of such a battery be connected to the galvanometer by means of the binding screw marked "+ or P," and the other binding screw be connected by the other wire, the north pole of the needle having been previously adjusted so as to lie between the two binding screws, it will be found that the N. pole of the needle will deflect to the *left* of the line of the coil; the operator being supposed to be standing between the binding-screw end of the galvanometer, and the wire of our coil returns *below* the needle, it is evident that a positive current (an outflow of undulations) passing over the north pole of a horizontally suspended needle, or a negative current (an inflow of undulations) passing *under* such a north pole, will tend to deflect to the *left*.

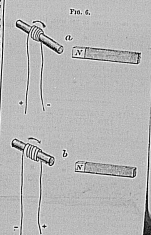
If we disconnect the battery, and reverse the connections, *id est*, put the negative pole (the wire coming from the stud) to the binding screw marked "+ or P," the other pole, coming round to the other screw, the opposite effect results—viz., the north pole now deflects the *right* of the coil. The will be understood by reference to Fig. 5, in which *a* represents the direction of a positive current flowing *from* the operator, round the needle, the N. pole in both illustrations being supposed to lie *into* it; in *b* the positive current is supposed to be flowing *from* the operator, *below* the needle, in either case returning to the battery *via* C.

§ 7. The effect will enable us at once to recognise, by means of our galvanometer, the *direction* in which a current is travelling; *for*, on connecting the two terminals of any source of electricity to the binding screws of the galvanometer, whether the N. pole of the needle is deflected to between the two binding screws, the operator facing the north pole of the needle, it is evident that if the N. pole of the needle is deflected to the *left*, the terminal attached to the binding screw marked "+ or P," is the one to which the N. pole inclined to the *right*; then the said terminal is *negative*. It must be borne in mind that the term *positive* in this connection is meant the point *from* which electricity is flowing, regarding the point *towards* which it is flowing,



or at which it enters.* This power of recognising the direction of a current will be found of great service to us in the construction of the dynamo.

§ 8. Returning now to our experiments with the magnet (see latter portion of § 3), and using in preference a straight soft iron rod, about 6in. in length, and ¼in. in diameter, rolled with about 1000ft. of No. 24 covered wire as our armature, and a good bar magnet to produce the electrical effects, we shall find, on coupling up the armature wires to the galvanometer, and approaching one end of the armature (*a*, Fig. 6) resting it from the N. pole of the magnet, that the electrical flow set up is always in one direction in approaching or making contact, and in the opposite direction on removing or breaking contact. Fig. 6 will make this clear. The arrow at *a* shows the direction of the current induced in approaching or making soft iron rod, about 6in. in length, and ¼in. in diameter, rolled with about 1000ft. of No. 24 covered wire as our armature, and a good bar magnet to produce the electrical



flow at, or when the N. pole of the magnet is approaching the end of the armature (*a*), resting it from the N. pole of the magnet, that the electrical

* All rights reserved.

* I have no desire to enter into any theoretical matters in connection with this subject; but, comparing electricity to water, we may say that following a kind of a transport, the transport may be considered as being *towards* the earthed *direction* may be considered as being *towards* the earthed terminal, whether it be positive or negative. The terminal from which electricity is flowing,

TELEGRAPHING BY THE DYNAMO-ELECTRIC CURRENT.—A plan for utilizing the dynamo-electric current in the Indian telegraphs instead of batteries has been devised by Mr. Louis Schwendler, and tried successfully. *The Journal of the Asiatic Society*, of Bengal, relates that one of the dynamo-electric machines used in lighting the sheds at Howrah Railway Station was selected to generate the main current which was conveyed to the Calcutta telegraph office by an ordinary telegraph wire two miles long. The strength of it at the beginning of the trial was carefully measured and found to be 36,801 millionths; one ampere being equal to one weber per second, and one millionth being therefore equal to one milliweber per second. At the Calcutta office eleven long telegraph circuits, running to Bombay, Madras, Kurrachee and Rangoon, were worked with currents tapped from this main stream for a period of three hours. The traffic was dispatched without accustomed regularity, and the signal currents were found by measurement to be stronger than the ordinary battery currents in use. The practical success of the trial has disposed the administration to introduce the system at the Calcutta office; and as there will be a large surplus of main current, Mr. Schwendler intends utilizing it for lighting and motive purposes. "The electric light," he says, "would produce at least fifty times less heat than if the same quantity of light were obtained by combustion; and this is no doubt a great advantage in a hot climate like that of India. During the daytime the main current might be used for working the pneumatic system of dispatching messages between the head telegraph office and local centres in Calcutta."

In regard to the heating powers of such a current, Mr. Schwendler says that if sent through an iron wire laid along the walls of a room like a hot water pipe, it would produce about as much heat as is given out by the ordinary German stove consuming six pounds of coal per hour, supposing that the loss of heat when coals burn under a steam boiler is about four times greater than when they burn in a German stove.

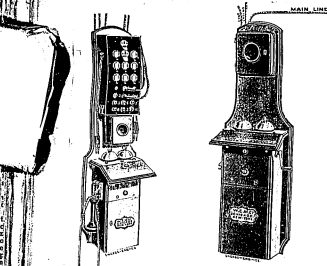
THE WESTERN ELECTRIC-MAGNETO CALL BOX. AND PONY SWITCH BOARD.

There is nothing in which the general public take such genuine interest as matters touching the wonderful results of the application of electricity to the common necessities of life. There is so much that is unknown and entirely mysterious in this wonderful force our electricians are experimenting with, and reducing to harness in some new discovery of the application of its power every day. All of us are glad to see some new device, or be informed of the application of one which has come into general use. The average woman is not heartily reconciled to the telephone yet; there still remains for her a mysterious air, a faint suggestion of witchcraft about it, or if of a sensitive temperament, too uncomfortable a realization of the tremendous force harnessed up for the occasion to prevent her feeling stress and nervousness the sound of that mysterious "Hello!" The truth of this is inditerously exhibited a hundred times a day in our large drug stores, where the clerks are annoyed from morning until night by timid suggestions from lady customers (who buy a ten-cent sponge, and consume half an hour's additional time) that "they can't hear," "are not yet used to it," "and must send a message," etc., until said clerks wish the telephone in Hades.

The Western Electric Manufacturing Company's establishment, on Kinzie Street, exhibits a great variety of telephonic apparatus manufactured by them. The illustrations below represent the Western Electric Magneto Call Box and the Pony Switch Board.

The Call Box, as seen in the illustration, is mounted on a base board with a battery box. The generator is compact



PONY SWITCH BOARD.

WESTERN ELECTRIC MAGNETO CALL BOX.

and powerful, and the bell, it is claimed, rings louder than any other in use. There is an automatic crank switch which is simple and effective, and the crank works the switch when turned in either direction. The telephone switch is so arranged that the circuit can never be left open. One of the special merits of the box is its compactness in form and arrangement.

The Pony Switch Board is made for factories and small exchanges, and is considered very complete. The number of wires for which it is made is for from ten to twenty-four lines. It is mounted on a base board with a magneto call box. The operation of the board consists simply in inserting plugs, with cords attached, in the spring jacks of the subscribers wishing to be connected. The annunciator drops and switches are the same as those used with the standard and duplicate boards; consequently they can be utilized should a larger board be required at any time.

Storing Electrical Energy.

Continued from page 21, March 1st.

The gases in the tube were formed by passing a galvanic current through the pair. The gases forming at each plate in well-known proportions. The battery being discommected and the plates connected by a wire, a continuous current is produced resembling that of a Daniell's element in electro-motive force. The current continuing to flow until the gases previously accumulated have recombined.

The current produced by the Grove gas battery is equal to the current which produced the gases by the decomposition of the acidulated water. A modification of this battery, affording greater surface of triple contact between metal, gases and acidulated water, pomlines the best of any form of storage battery for many uses.

In subsequent experiments Mr. Grove employed plates covered with peroxides of metals, and C. W. Siemens employed carbon tubes, very porous. The cooling gave a greater quantitive effect, with less intensity. The intensity was increased by coating the tubes by galvanic deposition of platinum before introducing them for charging.

In 1845, Wheatstone constructed what he was pleased to term a *galvanic* battery which employed platinum plates coated with peroxide of lead in contact with cloth soaked in solution of potassium; in describing the same, he says, "when a plate is easily exposed by making it the positive electrode in a decomposing cell charged with a solution of acetate of lead."

In 1852, C. W. Siemens con-structed a secondary battery by employing carbon plates impregnated and coated with peroxide of lead, in acidulated water; describing it he says: "The plates were dipped into a solution of acetate of lead. Then treated to dull redness, cooled, and again dipped in the lead solution. After repeating this operation several times the plates were acted on by galvanic currents by which the lead was converted into peroxide of lead. The current from the secondary battery thus formed gave two volts from a single pair. A larger battery of carbon plates thus coated and held separate by a porous partition gave good results."

The power of this form of cell depends upon the time of application as well as the power of the charging current. It affords a large amount of active surface in a small space, and is less expensive, and of less weight than batteries employing lead plates.

In 1859, M. Gaston Plante showed that lead was the most favorable metal for use in secondary batteries and he has since then multiplied proof of this superiority.

In its first form the battery of Plante consisted of sheets of lead held separate by a sheet or strip of felt, and rolled together to form a cylindrical shape or fit the jar, etc. This battery thus constructed was filled with acidulated water and the peroxide of lead formed on the plates by the first charge of a galvanic current.

In the first formation when the battery is new there is an advantage in polarizing the electrodes first in one direction and then in the other, and by reversing the current in each direction of the charge, but in subsequent uses care should be observed to always charge it in the same direction.

After the battery is "formed" the plates are found to be coated with a layer or crust of absorptive sub-stance that will receive and discharge electricity.

The number of times a secondary battery is charged and discharged the better it is. Intervals of rest improve this form of battery.

He connected four or five elements or cells side by side, and charged them from three Bunsen elements, and connected them in series for discharging. The secondary currents are able to magnetize electro magnets more powerfully than the primary currents from which they are derived.

It is found that when the resistance is considerable the current remains constant during several hours. It is found that a well "formed" element would give a good current several weeks after it was charged.

In order to obtain currents of great energy, a number of secondary elements are arranged side by side, and charged and connected in series to be discharged.

As commonly understood, Plante's secondary batteries are constructed only in view of scientific researches; he, nevertheless, used forms possessing industrial qualities. He employed the peroxide of lead as a cement or paste, pressed into spaces in a metal plate or electrode, in shape not unlike a gridiron.

In 1861, Charles Kleebhiel described several modifications of secondary batteries. One of these batteries consisted of metal plates coated with mercury and immersed in acidulated water or in solutions of sulphate of copper. He describes another, consisting of plates of metal coated with peroxide of lead and non spongy lead, by electro deposition in a solution of nitrate and acetate of lead. He describes using lead plates coated with mercury, and says: "Electricity from any source may be stored up, so, for instance, connecting these forms of batteries between a lightning rod and the earth to obtain atmospheric electricity, or with a reader of a fictional machine, or with a magneto-electrical machine."

In 1880, Gen. G. Percival employed electrodes for secondary batteries, consisting of plates coated with crystalline coke and powdered lead, in dilluted sulphuric acid.

In 1880, Mr. Percival published a description of an improved form of secondary battery, con-sisting of a positive electrode of coke, with a neutral solution of the positive metal, as Zn. Sn. &. By this means not only is peroxide of lead deposited on the negative electrode, but there is also a finely-divided deposit of zinc on the positive electrode, and sulphuric acid is liberated.

In this arrangement a much more-negative chemical, and consequently electrical action, is developed, when the charging current increases, than if both electrodes were of lead. He amalgamates the zincs.

In 1872, Deschwel, of Paris, employed a secondary battery, consisting of electrodes coated with metallic salts, mechanically applied.

He describes two electrodes coated by electro deposition, but says: "It is not necessary that the deposition of the sub-stances on the plates should have been brought about by electrolysis. A similar result will be obtained if the plates be coated with the substances in any other way."

In 1879, Count d'Arsonval employed carbon plates covered by oxides of lead and manganese, coupled with zinc plates in solution of sulphate of zinc.

It will appear from the foregoing that a secondary battery can be formed by the use of gases in the presence of unoxidized electrodes, preferably of platinum or carbon:

By electrodes of different character, whether of different metals or of the same metal, when surrounded or coated with chemicals of different character; or

By electrodes of different electrical potential, made so by galvanic action.

It has been shown in the foregoing that secondary batteries can be formed by the use of electrodes coated with an active layer of absorptive substance, such as metal or metal compound that becomes spongy, and thus capable of receiving and discharging electricity, that the electrodes have frequently consisted of plates impregnated and coated with oxides, insoluble salts, and amalgams of metals applied as a paste, by electro deposition or otherwise.

The electricity received into secondary batteries is not retained as electricity, but is held in a chemical embrace, and gives out the electrical energy by the action or chemical affinities as disclosed by Faraday in 1799.

In all the foregoing described forms of secondary batteries, the electricity that is used to charge them, passes through them and does not accumulate in the battery as some might suppose, but in passing through the battery it acts to create a difference in chemical potential between the positive and the negative plates which constitute the battery, and when these plates are fully charged in their chemical relations to each other, and the charging current increased to flow, these batteries are then simply galvanic batteries, and in the act of being discharged they lose their power like other galvanic batteries, but they can be charged whenever exhausted by the action of electricity passed through them, and do not consume zinc and chemicals which require to be replenished.

Galvanic batteries which consume zinc and chemicals give electricity at less expense, and if they had continued to be the principal mode of supplying electricity we should not have so much need of secondary batteries, as it would be as well to employ these batteries direct as to store their energy.

But chemical consuming galvanic batteries are too expensive for producing light and power.

The development of Faraday's discovery that the motion of a coil of wire in front of the poles of a magnet or in a magnetic field gives rise to an electric current in the wire, has shown us that the bunding of zinc or other materials in batteries, such as Grove's or Bunsell's, is a very expensive way of producing an electric current, and that it is far more economical to obtain electric currents by employing the best mechanical means we have to produce rotation of the coil of wire in the magnetic field. The different magneto and dynamo-electric machines that they abound are but the results of attempts to find the best form of coil, the best kind and best form of magnets, the best proportion of the-masses, and the most suitable arrangements for the special work in each case which is required to be done. The dynamo-electric machine is very satisfactory as a mode of producing electricity, and both the electromotive force and the current increase with the rate of rotation of the coil. This mode of producing electricity is like raising water to any level that may be required for any particular use; but the electricity must be used at once. This may be very inconvenient, and hence the necessity for something like a reservoir to store up the electricity. The labors of Faraday have shown us the relation between the quantity of electricity and the weights of the chemical elements decomposed by it, in electrolyte, and that these chemical elements may unite again to reproduce the compounds from other which will remain apart, even when joined by a liquid conductor, until a complete electric circuit is made. Then these two substances should be at considerable difference of potential, so as to give a strong electric current in uniting again to form the substance from which they were decomposed.

Besides these secondary batteries previously described, convenient forms are had by employing a scroll of copper and a scroll of zinc, arranged as in a gravity battery, in a solution of sulphate of zinc, or—

By employing plates of lead, disk shaped, filled with red oxide of lead, or peroxide of manganese, covered with cloth or like porous layer, and set one on to the other; a dilute solution of vinegar or sulphuric acid can be used. A secondary battery employing a negative plate of palladium, which absorbs the action of electrolysis absorbs more than 900 times its volume of hydrogen with a positive pole of lead, is well spoken of; good results are said to have been obtained by the use of iron turnings in place of the palladium plate, as it will absorb 200 times its volume of hydrogen in a solution of sulphate of ammonia of 50 per cent. of salt.

The negative electrode should have the property of absorbing hydrogen, and the positive pole should have the property of absorbing oxygen or of becoming peroxidized.

[*To be continued.*]

A Boston landlady, whose impecunious boarder owed her a bill of $50, was finally prevailed upon to take 18 shares of telephone stock, which then had no market value. She can now sell them for $3,000.

Electric Light vs. Gas.

A striking illustration of the economy of electric illumination over gas has been practically afforded for some time past at No. 182 Hegent street, London, England, in the studio and photographic establishment of Mr. Henry van der Weyde, the son of the editor of this paper. He takes photographs by electric light and same, and uses for that purpose a Gramme dynamo electric machine, driven by a gas engine consuming thirty cubic feet of gas per hour, and producing an arc light, which by help of a parabolic reflector illuminates the sitter with a soft, but no active light that a portrait is taken in six seconds. Now, the question arises, if this same amount of gas, thirty cubic feet, were consumed by a number of ordinary burners, say, six feet-burners, a picture could be taken by it in six seconds? Every photographer knows that this would be utterly impossible, and that the most sensitive preparations would require as many hours.

Or, to look at the matter from another point of view, thirty cubic feet of gas per hour is, per minute, half a cubic foot, and in six seconds one-twentieth of a cubic foot. *Question:* Is it possible to make a photograph by means of one-twentieth of a cubic foot of gas? *Answer:* It may be possible by the addition of combustion promoting chemicals to increase the quantity of light, but as it is possible to increase the heat produced, or the power by making an explosive mixture; but surely it is utterly impossible in the ordinary way of burning gas, which is very wasteful in all respects, not only in the production of light, as of heat and power.

It is, indeed, strange that in place of burning coal directly, it is more economical to employ the roundabout way of placing the coal in a retort, and heating it so as to transform its principal constituents into gas, and then, instead of using the gas directly, to burn it in a gas engine and generate power; then to transmit this power to a dynamo-electric machine, and transform it into magnetism and induced positive and negative electric currents; then to pass these currents over a conducting wire, and then place in the circuit so formed a few carbon points, and by separating them create a local resistance, by which the two opposite electricities, while neutralizing one another and appear ently disappearing are transformed into a more intense light and heat than it is possible to obtain from the fuel used in the ordinary way of combination.—*Industrial News.*

The Microscope and the Electric Light.

Mr. C. H. Stearns, F.R.M.S., recently brought an interesting application of the incandescence lamp to microscopy before the Newcastle-upon-Tyne Chemical Society. A small 8-candle lamp of two or three candle power is permanently attached to the microscope, and screws in place of the ordinary oil lamp, over which it has the advantage of requiring no cleaning, giving off no smell or much heat, and yielding a purer light. The great ease and facility with which the lamp can be adjusted is beyond comparison with the ordinary gas or oil flame, especially when the light has to be shifted to above or below the stage for illuminating opaque or transparent objects. Condensers may also be got rid of by its use. The light of the lamps controlled by a small resistance coil, and two or three Grove or Bunsen cells are sufficient to work it. Where the battery must go with the instrument, and the latter is placed in a drawing-room or study, the inodamatic or lithonomatic batteries are preferable, as they give off no offensive fumes. In Mr. Stearns' micro-scope, as shown to the society, there are three lamps—one above the stage revolving round its own axis, one below the stage fitted to the sub-stage, and one below the sub-stage for use with the polariscope. Each lamp is connected with a three-way switch, which sends the current to either lamp at will. Mr. Stearns also arranges the fittings so as to shift a single lamp to any of the three sockets mentioned, and thus save expense in lamps.—*Engineering (London).*

Cost of Electric Lighting.

The Fuller Electrical Company make the following estimate as the cost of electric lighting by their system:

"Owing to the various conditions under which intending users are placed—some already having ample power, either water or steam, while others have boilers, but no engine—it is impossible to give figures applicable to every case. It is therefore well, we think, to let each individual establishment figure power for themselves.

"In forming a fair estimate of cost of lighting, the matter seems, naturally, to divide itself into two parts; firstly, *cost of installation;* secondly, *cost of maintenance.* The first includes apparatus, dynamos, lamps, wire, services of competent men to properly prepare the plant for operation; *to which* must be added engine and boiler, shafting and pulleys, if these are not already available. Where the last are already in place, it is obvious that the *first cost* of electric lighting is very much reduced. The second division includes a fair charge on the investment on interest account; depreciation, which may be said to include wear and tear; carbons, attendance and power.

"By reference to our testimonials, it will be seen that electric light apparatus requires no more attention than any other well constructed machinery. It is erroneous to suppose that the services of an electrician or expert are required after the first twenty days, during which the Fuller Company leave their men in charge.

"A twenty light apparatus is an ordinary sized one, and we select it for purposes of estimate. Supposing we have a machine shop, mill or large store, hotel or factory to light, under ordinary conditions and circumstances, we make the following estimate:

TWENTY LIGHTS, FULLER SYSTEM, Dynamo No. 2. No. 20 Spool Gramme	$2,000 00
Lamps—20 Weeks' Patent, @ $50 each	1,000 00
Wire—Say 1,000 feet, 38 p. per foot—10 feet to the lb., @ 35c. per lb.....	35 00
Cost of running circuits, about.....	100 00
	$3,135 00

"The cost of maintenance, including carbons, attendance, interest on investment and depreciation, is so moderate as to render this mode of lighting unlimited to owners of isolated plants requiring large spaces to be lighted, and also to afford a handsome profit to persons making inquiries for the renting of lights, at rates which they readily command wherever introduced.

"The above machine requires not more than fourteen effective horse-power. For those unaccustomed to figure cost of power on a basis of steam, we append the following figures, which we believe are those ordinarily recognized by competent engineers:

When fires are built afresh each day for express purpose of running electric light apparatus, the coal necessary each hour to develop one effective horse-power is..... 4 lbs.

When fires are constantly on and power is applied for other purposes, driving shafting, running elevator or heating, the additional coal necessary to develop one effective horse power *additional* is..... 2½ lbs."

Electrical Motors.

It is intimated that experiments will soon be made with a view of introducing electricity as a motive power on the elevated roads in this city. These experiments, which are to be made on the Thirty fourth street branch, will be conducted by Mr. Stephen B. Field, the electrician for the Mutual Union Telegraph Company. Mr Field has been at work experimenting with electric motors for a long time, and claims priority in his ideas to both Siemens the originator of the electric railroad in Berlin, and Edison, whose road at Menlo Park has been running for experimental purposes for over two years. Mr. Field first began his experiments several years ago, and afterward, at Stockbridge, Mass., constructed a road forty feet in length, upon which, with a dynamo-motor car run by a 2½ horse-power engine obtained results which fully satisfied him that the elevated railroad cars in this city can be run much more cheaply than at present, and without the smoke and noise which render the roads a nuisance at present. Mr. Field has obtained permission from the managers of the elevated railroad to thoroughly test his experiments on the Thirty-fourth street branch, and says that several capitalists have promised to aid him financially in carrying them out.

According to Mr. Field's system in case of the adoption of electricity on the roads, of which he has no doubt when his experiments have been submitted to the management, there will be two stations or plants where the power will be generated from large dynamo machines. One of these stations would be placed at the Battery and the other at the Harlem river, on account of facilities for getting water necessary for the engines that run the dynamos. After the electricity is generated, it will be conveyed over to the present rails or else to a supplemental rail which could be laid in the centre between the tracks. The current running through the rails is then taken up by the wheels. By the simple turn of the lever in the engine the circuit can be broken and a train stopped. Any number of trains can be moved from one station to another, and all would be under the control of men at the stations, or even at the central station. The motor would be noiseless, Mr. Field declared, and of course there would be no smoke, cinders, or clouds of steam. By the system, various sections of the road could be divided into blocks in which only one or two trains would be allowed, thus increasing the safety of travel to a great extent. "In fact," said Mr. Field, "the trains would be under perfect control. If a train was at one station, the trainmen there could positively prevent another from coming up to it. Precaution has been made for the stopping and starting of trains, also for the running of any number on the same circuit without the motion of one exerting upon others to any damaging extent." In regard to brakes, Mr. Field's idea was that they should be operated by electricity or compressed air, whichever should prove the most convenient for the purpose. If electricity was used, it would probably be taken from storage batteries. In the plan probably to be adopted, storage batteries would be used any way to furnish the electricity for lighting the cars. This power could be derived from the rails while the trains were at a stand-still at stations. Alarm mechanisms or whistles, if their use was necessary, could be actuated by compressed air. According to one of Mr Field's plans, the locomotive is dis-united altogether, the power being applied to the trucks of each car. In this manner an increased number of cars could be carried with each train, and it was a pet idea of Mr. Field that a short car should be placed at the front of the train, to be fitted up as a smoker, which would be used in the same manner as the dummies now drawing the trains. "However," said Mr. Field, "if an engine or motor is used, the entire weight for a forty horse-power locomotive would not be much over 10,000 pounds, or five tons, which I think much lighter than those now used."

In regard to the cost of running trains, Mr. Field thought it would be at least fifty per cent. less than under the present steam system. An engine now required from eight to ten pounds of coal per hour for one horse power. With the electric power on tracks, the expenditure would not exceed five pounds per hour to produce one horse-power. The wear and tear on the structure would also be much decreased, as the trains would run smoothly, and the motion would be uniform.

Mr. Field said that his claims of patents antedated those of Edison or Siemens. There was much litigation over the patents, but Mr. Field was confident that he would come out ahead. He was fully assured of the success of his motor, and thought it simply a question of time before it would be introduced on all the elevated roads in the city.

Mr. Thomas A. Edison said that Mr. Field was one of the men who were fighting over patents. Already the testimony had been taken, but he did not think the matter would be settled for a long time, perhaps not for over a year. If the elevated roads should run electric motors, both Mr. Siemens and himself should consider it an infringement of their patents. Mr. Edison claimed priority in time over Siemens, and also Mr. Field, and thought that it would be so decided by the Examiner of Interference in Patents, before whom the matter was pending. Mr. Edison did not believe that the elevated people would introduce any new system as long as it was controlled by the present management. Mr. Edison said he had commenced his experiments with electric motors in 1869, and had run trains at times over since at Menlo Park. He had now a freight and two passenger cars on the two-mile road at that place, and had also run three engines at a time on the road. His experiments had been suffering in all but an economic view, and of late he had made great advances in that point. A light train he could now run 45 per cent. cheaper than by steam. If it was heavily loaded with freight, the reduction would amount to only 30 per cent. He was now at work constructing a large engine of over 300 horse power, which he intended, when it was completed—and it would be finished in the spring—to try on a regular railroad, the Pennsylvania probably. This engine would be experimented with in carrying freight. Mr. Edison also stated that at Boston, next August, he intended to build a short road, upon which his electric motor would be run. As soon as the difficulties concerning the patents were settled he would be prepared to take contracts for furnishing the locomotives. On his road at Menlo Park, already a speed of forty two miles had been acquired, and the success of the system was assured. He thought a supplemental track should be used, so that both electric and steam trains could be run.

In reference to the elevated roads, Mr. Edison thought that the best use they could make of electricity, at present, would be to fit up the stations with continuous elevators, such as were used in several buildings in London. These elevators could be fed with electricity by means of wires from a central station, and the expense would be very light. —*Ex.*

Limits of Telephone Action.

The power of the telephone to transmit the voice to long distances is intimately associated with its delicacy. Mr. Willoughby Smith has found by experiment that a telephone will work through a "resistance" of wire corresponding to 150,000 miles of telegraph line; and hence it would seem possible a child's play to fulfill the words of the poet, and "waft a sigh from Indus to the Pole." But this was only a laboratory experiment; for on actual telegraph lines the leakage of electricity from the wire to the ground, damp, and other drawbacks, render the transmission of speech by wire for long easy in practice than was at first supposed. Nevertheless, it is on record that Mr. Edison transmitted speech over a line 250 miles long in America; and conversation has been carried on over 500 miles in India; 390 miles, from Tabriz, in Persia, to Tiflis; and 700 miles in Spain, Australia, and other places where the atmosphere is dry and pure. In England, we have not been able to work through such long circuits, owing to the wetness of the atmosphere; but Mr. Van Rysselberghe, the inventor-Chief of the Meteorological Observatory at Brussels, has telephoned from that city to Paris, a distance of 215 miles; and this while the same wire was carrying simultaneously an ordinary Morse telegraphic message. By a peculiar disposition of his apparatus, Mr Van Rysselberghe spoke to Paris by telephone without any interference from the Morse signals that were traversing the identical wire at the same time.

The day after the bombardment of Alexandria, it was announced in the London papers that the ends of the cable had been heard at Malta by telephone through 1,000 miles of submarine cable. Experienced electricians took the statement with a grain of salt, because they knew that a submarine cable differs from a land telegraph wire in the greater retarding effect which it has on electric currents traveling along it. A cable has the effect of condensing together—jamming up—the delicate and rapidly succeeding vocal currents of the telephone, and thereby muddling the articulation or creating absolute silence. Five hundred miles of land-line would make little or no difference in the distinctness of a telephonic message, supposing the wire to be well insulated from the earth; but two miles of ordinary submarine cable will probably be quite enough to spoil some experiments made by the wire, with Dr. Muirhead's artificial cable. Since the cable the voice could be faintly heard through a length equivalent to fifty, or even sixty, miles, when it came to a cable when sound at all was audible. The inductive retardation had frittered away and blotted out the delicate undulations of the vocal currents. Telephonic messages have, however, been successfully sent by cable across the Channel, and from Holyhead to Dublin; but in no case has the length of cable reached 100 miles. The dream of whispering across the Atlantic under the "roaring forties" is likely to remain a dream for along time to come.—*Chambers's Journal.*

Electricity and Ears.

It is gravely affirmed in a floating paragraph that a person in Texas having had to use a telephone a great deal during eighteen months, found to his dismay that his left ear, which he constantly applied to the instrument, had grown to three times the size of his right ear, and that it still continued growing.

Mr W. H. Eckert, General Superintendent of the Metropolitan Telephone and Telegraph Company, said, when asked what he knew about the effect of electricity on the ear:

"Well, I never heard of any such property as this thing as the statement in that paragraph. I have heard it said that the use of the telephone was injurious to the hearing, but from the facts within my knowledge I do not believe to pronounce that absurd. I have been in the business, in Cincinnati and here, since 1878, and have never yet to add any complaint whatever of such an effect from operators who were steadily at the receiver of a telephone circuit hours out of every day for months and years. I would certainly have known of it if there had been anything of the sort. The source of the trouble is probably be made is by the effect during a thunder-storm, and I know that that produces no uncomfortable feeling, and is attended with no danger. We never stop work on account of thunder-storms, nor did we do so in Cincinnati. In Cincinnati our receivers in the main office were all stationary, and fixed to the left ear. In addition to these, however, I had put in at first receivers with flexible connections, that the operators might use on the right ear in case of necessity. After a time it appeared that these were useless, and I gave an order for them to be removed. One distinctly a young woman—a very nice girl and one of our best operators—sent in her resignation. I saw her, and asked her why she was the reason for her going away. She was crying, and said that no one had ordered it impossible for her to do her work and so she had to leave. It then appeared that she had always been using the right ear, though we had never suspected the fact of the kind in the 20 or 30 that we had with us. Of course I left it to the discretion of the people, and this was one of the best receivers. She was dead before I came to us."

Six years ago on February 12, 1877, the first public exhibition of the telephone in Lyceum Hall, Salem, Mass., was reported being sent to telephone in the *Salem Gazette* and printed the next morning.

The "Ferranti" Dynamo Machine

IN September of last year, a considerable stir was caused in electric lighting circles by a statement of Mr. Hammond, made at a meeting of the numerous "Brush" companies, as to the capabilities of a new dynamo machine, with which the name of Mr. Ferranti was associated; and which, it was said, had been practically perfected. The statement of Mr. Hammond was to the effect that the machine in question was five times as efficient as any then in use, or, in other words, that it would give results equal to five times those obtained by the employment of any other dynamo. In many quarters this description of the possibilities of the invention was received with some amount of incredulity, and almost with ridicule; but among those interested in the financial success of the "Brush" subsidiary companies, in some of their "concessions" becoming in a great measure valueless was not unnaturally viewed with no little alarm. The "Brush" dynamo was notoriously ill adapted for incandescent lighting, and the announcement that the new machine was specially fitted for this class of work therefore materially helped the scare. Much speculation of course, followed as to the nature of an invention which was said to be capable of yielding such results, and it was afterwards learned that the great feature in the new machine was the absence of iron in the revolving armature. Very greatly decreased in weight, and, by enabling the field magnets to be brought very close together, greatly increased in efficiency. It was not until the end of November that there was a public demonstration of the light-producing powers of the dynamo, but it was generally felt that what was witnessed by the electricians and others assembled on that occasion indicated—if not the accomplishment of all that was predicted by Mr. Hammond—certainly real and very considerable progress. A full account of the exhibition appeared in these columns at the time. A small alternating current machine was shown running no less than 300 lamps of 20-candle power each, and in steadiness the illumination left absolutely nothing to be desired. On examining the machine every one was struck with the very small weight of metal contained in the revolving armature. As most systems the armature is of very bulky dimensions, the result being that any endeavour to multiply the size of the machine would lead to the making of an armature quite unwieldy in its proportions. It was of such a construction that it could be enlarged to almost any extent with a corresponding increase in electrical results. Indeed, we were assured on that occasion that the 300 lights, and that a machine to give 2,000 lights, which was then in course of construction, would be only very slightly larger.

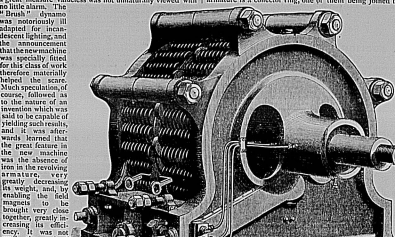


FIG. 1.

The holders of the Ferranti patents have since been devoting themselves to the practical and commercial development of the system. In view of the great extension of electric lighting which is anticipated upon the passing of the numerous provisional orders approved by Parliament, and more particularly in readiness for the needs of their own district of Hampstead, Messrs. Ferranti, Thompson, and Ince have been making more powerful types of their machines, and have also recently introduced many changes which have resulted partly from additional extended experience, and partly from the aforesaid greater demand for machines as compared with small ones. We are indebted to *Engineering* for the accompanying engravings illustrative of one of the larger machines of the latest type. Much of the description which follows is necessarily technical, but its general purport will, doubtless, be fully understood. Fig. 1 is a view of the complete dynamo, which is designed to supply no fewer than 5,000 lamps. It comprises three principal parts, each of which is self-contained. These are the armature (Fig. 2) and the two sets of field magnets (Fig. 3). The former consists of 10 discs or bobbins insulated from each other and from the shaft, and carrying between them an insulated ring. To the periphery of each disc is fastened an equal intervals eight copper strips 11 in. wide and 1·75mm. thick, and these strips are then bent into the undulating form shown in Fig. 2, each strip making the circuit of the whole periphery of the armature twice and being secured at its outer end to a rivet in electrical contact with one of the discs. Thus, as the strips are divided from each other by insulating material, there are eight parallel circuits around the armature, the ends starting from the internal brass ring and ending after two revolutions, in the case of the smallest, at the same point. At either side of the armature is a collector ring, one of them being joined by a heavy copper connection (Fig. 2) to the internal brass ring, and the other to the opposite disc, so that the two rings form the terminals of the armature circuit. The current is not taken off by brushes in the usual way, but by solid rubbing pieces (Fig. 2) which embrace both sides of the collector rings, and are held up to their places by springs. The current is led from these collectors down heavy copper bars enclosed in a casing on the outside of the framing (Fig. 1) to two terminal studs, by which it is transmitted to the main leads. The suitable diameter of the armature is 9 ins., and its speed rather less than 1,000 revolutions per minute, at which rate it will furnish some 2,000 amperes of current with an electromotive force of 200 volts. As the machine is separately excited from an independent generator, and as its internal resistance is exceedingly small in comparison with that of the outside circuit in which it will be applied, it follows that the difference of potential at the terminals of the station varies exactly with the number of lamps in action, the power absorbed by the machine increasing and falls with the number of light produced, and there is no waste of energy.

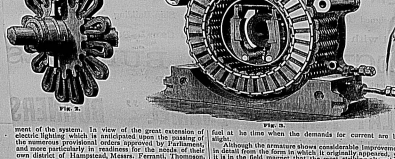

FIG. 2.

FIG. 3.

In the field magnets (Fig. 3) the cup of the armature fits between the two sets of field magnets (Fig. 3). The former consists of 10 discs or bobbins insulated from each other and from the shaft, and carrying between them an insulated ring. To the periphery of each disc is fastened an equal intervals eight copper strips 11 in. wide and 1·75mm. thick, and these strips are then bent into the undulating form shown in Fig. 2, each strip making the circuit of the whole periphery of the armature twice and being secured at its outer end to a rivet in electrical contact with one of the discs. Thus, as the strips are divided from each other by insulating material, there are eight parallel circuits around the armature, the ends starting from the internal brass ring and ending after two revolutions, in the case of the smallest, at the same point. At either side of the armature is a collector ring, one of them being joined by a heavy copper connection (Fig. 2) to the internal brass ring, and the other to the opposite disc, so that the two rings form the terminals of the armature circuit. The current is not taken off by brushes in the usual way, but by solid rubbing pieces (Fig. 2) which embrace both sides of the collector rings, and are held up to their places by springs. The current is led from these collectors down heavy copper bars enclosed in a casing on the outside of the framing (Fig. 1) to two terminal studs, by which it is transmitted to the main leads. The suitable diameter of the armature is 9 ins., and its speed rather less than 1,000 revolutions per minute, at which rate it will furnish some 2,000 amperes of current with an electromotive force of 200 volts. As the machine is separately excited from an independent generator, and as its internal resistance is exceedingly small in comparison with that of the outside circuit in which it will be applied, it follows that the difference of potential at the terminals of the station varies exactly with the number of lamps in action, the power absorbed by the machine increasing and falls with the number of light produced, and there is no waste of energy.

The electrical details of the generator have been designed with great care. Each bearing, both cup of the armature and in addition to this three oil pipes in connection with a pump driven by the crosshead, and through these latter lubricants can be forced if the ordinary means fail to keep the bearings cool; all the parts are made interchangeable, and the whole machine can be entirely taken to pieces in a short time. At present we are not in a position to give any account of its performances; but as we believe that no other firm, except the Telegraph Construction Company, has as yet attempted the manufacture of a machine of such dimensions with the ambitious objects in public lighting which have been put forth, we are sure that the public will await with interest the results of the process has attended this attempt to provide apparatus for electric light undertakers suited to the responsibilities they have undertaken.

The current is led through the filler ropes, made for the purpose, and twisted wires, covered with silk and cotton, and encased in an India-rubber tube, to what is called the *governmental motive propellers*, or combined rudder and propeller.

The electrical motion, designed by M. Trouvé, while in many ways similar to the Siemens coil, has been made by modification so as to secure more efficiency than that before in use, when this was applied to marine architecture. It is placed in the rudder-head while the propeller itself revolves on a slot in the rudder itself, motion being communicated by an endless chain. So great is the action of the rudder intensified by this arrangement that, unlike its prototype propelled by steam, this boat can be made to turn almost on her own centre. Thus a complication of machinery required in order to permit of a boat's forward movement being reversed, is rendered unnecessary. The filler ropes are provided with contacts to enable the steersman to instantly stop the movement of the boat or start or back her. By taking off the rudder, which can be performed in a few minutes, the boat is ready for towing, and always make sure, while anchored in unfrequented waters, that no one will run off with her.

So far, all that electrical boat travel through the water that, at a normal rate, a four-oared gig or racing boat going at full speed can usually overhauled and passed by her.

Now, there are said to be over two hundred electric boats, built upon the model of the Tarolea, navigating French and English waters, and constructed are being made for the construction of many more.

We look forward with appreciable enthusiasm to the construction of one of these craft *for our own waters*, in the full conviction that, when its many advantages are thoroughly comprehended, the building of a fleet of them will follow.

The electrical boat glides smoothly and quickly over the water. There is no smoke and no disagreeable odors. Instead of the cumbrous engine and huge coal bunkers, to fill which the craft must be covered with coal dust, there are accommodations for passengers, the batteries taking up but little room in comparison.

Again, as is well known, the engine of a steam-launch is, unless watched with great care, liable to breaks and even more serious accidents. The pumps and gauges are so small that they are easily clogged up, and when the water in the boilers, as it is not an unusual thing for the water-gauge facing the cabin, to register "full" when it is the boiler when in reality there is hardly any at all, and many an excursion party has been surprised to see the engineer suddenly open his doors and draw his fires as if life itself depended upon his getting them out without a second's delay, which in many instances has been known to be the case.

No such dangers attach to the use of the electrical boat. Of course, when a continuous journey is contemplated, the electrical boat could not at the present time be used for the reasons that there are, as yet, no electrical stations established to supply the supply of electricity could be had when the storage battery aboard had been charged. Until the establishment of these however, the boat may be run until half the stored power of its batteries is drawn off, and return trip made with the batteries only.

The lines of force diffused between when electrical storage stations will be found on the banks of all populous watercourses and the power of the charged boat can obtain a new supply of electrical power without difficulty, and at a cost so trifling as to be quite an item in the expense account, comparatively speaking.

The American District Telegraph Co. has filed papers in two suits against the Postal District Messenger Co. (Limited) and Postal District Telegraph Company, for infringement of patents of Prof. A. E. Dolbear, of Providence, R. I., and Rogers and Cowen, of Boston.

On the Composite Character of the Induction Spark.

By CUNT DE MOSCEL.

(*Translated for the* ELECTRICAL REVIEW *from* *Le Lumière Electrique.*)

We have already spoken several times in this journal (*La Lumière Electrique*) on these two lines of theory, chiefly in connection with the subject of magnetic reactions on the induction spark, but the matter is treated more fully in our number of June 16th, 1883, a bearing of the various forms of the electric arc. We, however, must here, deem it to be well to return to the subject at this time, for the reason that the preceding article was discussed very briefly, and in all works treating specially of static electricity, M. Mascart's theory of sparks, the matter has been dismissed in a few lines.

I had already treated of this subject in the latter volume of my notice on the Ruhmkorff apparatus, but in my pamphlet on the non-homogeneity of the induction spark, I have treated it with all the fullness due to the subject although I will now give a summing up of that work.

It is noteworthy that all the effects in question were much better developed and more easy to observe in the earlier Ruhmkorff machines than in those used at present. The modern makers seem to have aimed at the single end of producing the spark, and to reach this result they have sacrificed quantity to quality, and by their *new mixture in the secondary coils: At first thin wire and dense; then thick wire, thickened, and the* ...ubbins longer, and, if the experimentalist ...obtained ...very 2 centimeters long, they were well suited, composed by a dense smooth, and productive of calorific effects much more intense, for the same battery, than those of the former, but they were not, as we shall, therefore, speak of the effects produced by these earlier machines in this article.

If we attentively examine the Ruhmkorff coil induction spark, we first notice that it is not simple, and that it is composed of several luminous disks of extreme whiteness, surrounded by a species of sheath or luminous envelope of a dull greenish red, which seems to be formed by the luminous atmosphere, and which is sensitive to the movements of the surrounding air. It is this envelope which Mascart has called the *aureole*. It is produced by a layer of air heated by the spark, and this layer, in proportion to the electricity thus acquired, serves as a vehicle for the transmission of the greatest portion of the charge. The spark, then, is composed of two distinct portions—one represented by the flashes of light of the direct discharge, which constitute the spark, properly so called; and the other represented by the aureole, which is only a discharge transported by an ...form conductor, and which restores under

FINANCIAL AND MINING NEWS.

Storing Electricity.
Insert Advertise.

A company has been formed in this city which is expected to occupy a prominent position in the process of storing electricity for lighting and other purposes. Its patents are now before the Commissioner of Patents at Washington, and if all the claims of the Newark organization are granted the celebrated Frenchmen, Faure, and the hardly less famous Brush will lose some of their titles to consideration as discoverers.

The Newark company claims priority in the invention of the true system of storing electricity, of which M. Faure has been said to be the prophet and inventor. The electrician of the company, whose inventions the corporation holds and proposes to operate, is Nathaniel S. Keith, of New York. The company is named "The American Electric Storage Company," and its directors are George W. Hibbard, Henry Young, George O. Frelinghuysen, Barker Gummere, Jr., and F. T. Fenny. Mr. Keith claims that two years before Faure secured his French patents he (Keith) and discovered the principles of the storage of electricity, and that to him belongs the right of the invention. The patent asked for is not on the principle of electric storage, however, but on the process of constructing the reservoirs. As is known, the great thing desired in electric lighting as to its practicability has been demonstrated, has been accomplished by which the lights were not dependent on every stroke of an engine for continuity. The storage of power as every master mechanic knows, has been one of the great problems in mechanics, and its necessity was seen at once in electric lighting. If the lamps were only to burn when the engines were working, it was seen that the time would come when the engine might give out and leave every customer without a light, and it was also evident that the engines could not be kept working night and day to supply the demand which ceases at all hours. Storage was a necessity.

The Faure, Brush and Keith inventions step to at this point. They provide a box reservoir composed of a series of lead plates into which the electric current is forced. The electricity produces a chemical action on the plates which forms a "potentiality of electric force," which will discharge the electricity in almost the same volume as received. The Keith invention differs from the Faure and Brush principally by the use of pure lead plates in the reservoir, instead of red lead. The pure lead yields much more rapidly to the action of the electric current and the reservoir may be prepared for use in far less time. The reservoir will discharge ninety per cent. of the electricity it receives, and the inventor claims that the properties may be made even larger.

The system is now in working order at the company's office, No. 792 Broad street. The storage reservoir is a box eight inches square in one corner of the room. It is filled with a series of lead plates, and altogether weighs about forty pounds or less. Into the box is conducted a wire from the electric generator in Mechanic street, which supplies the reservoir. The Mechanic street engine runs eight hours a day, and thus supplies the reservoir with sufficient electricity to supply incandescent lights for seven hours, provided the lights use up in one hour as much electricity as the generator supplies in the same time. From the box extend wires connecting with beautifully executed incandescent lamps of both the Weston and Edison make. The light is perfectly steady, and in color is between the yellow gaslight and the perfectly white light of the sun, having a pleasant effect on the eyes. Various forms of lamps may be used, and the reservoir will supply any number, thus attaining more perfectly than at any time heretofore the great desideratum of a wide distribution.

After the reservoir is once prepared for his work (which takes forty hours with the Keith and 800 hours with the Faure) it needs nothing but the electric current, and therefore works as simply as a reservoir of water. It may be filled at any time and to the full extent of its capacity, or it may be supplied with only enough electricity to keep the lamps running for a single evening. In factories furnishing the motive power of electricity to the reservoirs, the latter would be filled at night, when the power was not used for other purposes. The reservoirs are portable and when supplied with electricity to say running distance may be detached from the supply wire and used anywhere. The stored electricity may be used not only for lighting, but for running sewing machines, turning fans, pumping water, etc. The current is governed by a key similar to that used for turning gas on or off.

The American Company does not intend to go into the lighting business itself, but will sell its licenses to other companies which will apply the process practically.

A New Electrical Street Car.

A STORAGE BATTERY THAT WILL PROPEL A CAR FOR SEVEN HOURS — THE ELECTRIC POWER COMPANY DOING GOOD WORK — CHEAP, SAFE AND EXPEDITIOUS PROPULSION — FUTURE PROSPECTS.

The newly devised electrical street car has been illustrated for the benefit of the readers of the ELECTRICAL REVIEW, not by reason of its perfection as a motor, which as yet, it is not assured, but because it would seem to be the exponent of that system of electrical locomotion of which the charged rail and running wire constructions were the pioneers.

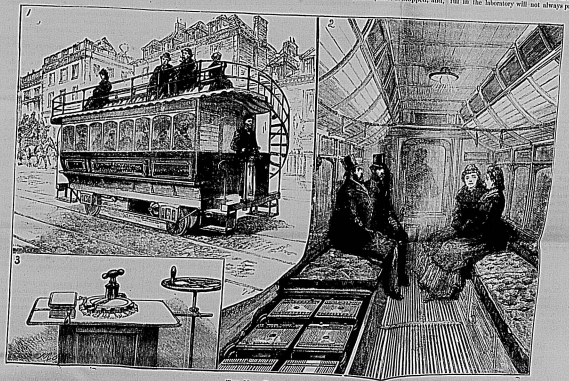
The car, a faithful representation of which is here given, was recently tried on the lines of the West Metropolitan Tramway Company, from Gunnersbury Station to Turnham Green, and thence back to Kew Bridge. Upon the morning of the day of trial the car was tested in the presence of the Government Inspector, on the Acton line, and had abundantly demonstrated its ability to do that which had been claimed for it. Smoothly and noiselessly it ran hither and thither, partly filled with passengers, of which it has accommodations for forty-six. The rate of speed attained was six miles an hour, though considerably more than that was shown to be possible.

As everyone knows, trial tests of newly devised machinery are rarely satisfactory, and at such times accidents seem more frequent than at others, where less critical observers are at hand. The electrical car was fated to meet with one, and, by an and after successfully traversing a part of the line in the afternoon's trial, a portion of the machinery, presumably the belts of the driving gear, got out of order, and, while taking from the number of cells by means of an ordinary electric switch, by breaking the circuit the motive power is stopped, and, with the axle of the wheel. Nearly set in the body of the car is an accumulator, consisting of fifty Faure Sellon-Volckmar cells, each measuring 13 in. by 11 in. by 7 in., and weighing about 80 lbs. The power of this accumulator is capable of supplying a constant motive power in the car for seven successive hours. Of course, the duration of the motor may be reversed at will, and, by an ingenious contrivance, the power may readily be increased or diminished, by adding to or the brake being then applied, the car is quickly brought to a standstill.

The car, with the accumulators and machinery, weighs 4½ tons, and when loaded with the forty-six passengers which it is designed to carry, there will be a total weight of 7 tons on each wheel. It has been computed that the daily cost of working the car, including first cost and wear and tear, &c., &c., against 30s. the daily cost of keeping horses.

For several years electricians have been busily engaged upon the various problems connected with electric lighting and have, with few exceptions, paid little attention to electric locomotion, which, there is reason to believe will, at no distant day, be considered of primary importance. The efforts of those few persons who have employed themselves in applying electricity to locomotion have not, up to the present, been rewarded with a very flattering measure of success. The road electrically operated between Berlin and the Sindenbrunnen, and the other and some what similar experiments in other countries, have but demonstrated that their projectors, if not their engineers, were on the wrong track; that what has proved successful in the laboratory will not always prove feasible commercially; and, doubly, that the cost of maintaining a unit of electrical railway is to the cost of a unit of railway operated by horse-flesh nearly as two is to one.

In the two-rail system, whose currents from powerful electric generators were sent along the rails and picked up by the car-wheels as a return, the public, which it was designed to benefit, were placed in great danger. Men, women and children were seriously injured by coming in contact with the non-insulated electric mains, and horses, while trying to cross the track, connected both mains with their body, were instantly killed. The third system, also, has not as yet proved any-



THE NEW ELECTRIC STREET CAR.

THE EDISON-HOPKINSON DYNAMO.

ELECTRIC MACHINE.

THE following abstract of the report by Mr. Frank S. Sprague on the Edison-Hopkinson dynamo-electric machine will be found of interest to electrical engineers :—

Characteristic features of the dynamo are : General arrangements.—Use of a shortened and differently proportioned Edison dynamo. The pulley, however, is outside of bearing, and with a face of 6½ inches. Diameter of 10½ inches projects 8½ inches outside the iron plate. Field coils wound over 3-inch core with ten layers of No. 16 copper wire (B.W.G.). Two legs in series. Armature : Diameter of core 9 inches, 74 c.-ds, single turn, 8 strands of No. 16 wire, average length 43 inches. Wire bound. Diameter 10-1 inches, with 3-inch clearance from pole face. Zinc plate connecting pole faces. Number of magnets not stated. Resistances : Field coils, 36·5 ohms ; armature coils, 0·06 ohms. Field measured ; armature calculated. Total resistance of circuit, armature varies, 0·235 ohms. Power supplied from a Lawrence —Armington and Sims—engine, high-speed and non-condensing, driven by a link belt through an Allerech tension belt dynamometer.

Engine diameter	8½ inches receipted.
Stroke	9½ inches measured.
Piston-rod	1¾ inch "
Fly-wheel	40 inches "
Indicator spring	50 inches "

The Ferranti Dynamo Machine.

In an interesting descriptive article of this machine our esteemed contemporary, *Engineering*says that in view of the great extension of electric lighting which is anticipated upon the passing of the numerous provisional orders now before Parliament, and more particularly in readiness for the needs of their own district of Hampstead, Messrs. Ferranti, Thompson, and Ince have been making more powerful types of their machines, and at the same time have introduced many changes which have resulted partly from their extended experience, and partly from the altered conditions of large machines as compared with small ones.

The dynamo which we illustrate on this page is one of these, and is designed to supply 8,000 lamps, each requiring a current having an electro-motive force of 200 volts, and an intensity of .33 amperes. It comprises three principal parts, each of which is self-contained. These are the armature (Fig. 2) and the two sets of field magnets (Fig. 3). The former consists of two discs or bosses insulated from each other and from the shaft, and carrying between them an insulated brass ring. To the periphery of this ring there are fastened at equal intervals eight copper strips 1¼ in. wide and 1·75 mm. thick, and these stripes then bent into the undulating form shown in Fig. 2, each strip making the circuit of the sinuous periphery of the armature twice, and being secured at its outer and too ether in electrical contact with one of the discs. Thus, as the strips are divided from each other by insulating material, there are eight parallel circuits around the armature, each starting from the internal brass ring and ending, after two complete revolutions, at one of the bosses. At either side of the armature is a collector ring, one of these being joined by a heavy copper connection (Fig. 2) to the internal brass ring, and the other to the opposite disc, so that the two rings form the terminals of the armature circuit. The current is not taken off by brushes in the usual way, but by solid rubbing pieces (Fig. 3) which embrace both sides of the collector rings, and are held up to their places by springs. The current is led from these collectors down heavy copper bars enclosed in a casing on the outside of the framing (Fig. 1) to two terminal studs, by which it is transmitted to the main leads. The middle diameter of the armature is 30 in., and its speed rather less than 1,000 revolutions per minute, at which rate it will furnish about 2,000 amperes of current with an electro-motive force of 200 volts. As the machine is separately excited from an independent generator, and as its internal resistance is exceedingly small in comparison with that of the outside circuit, to which it will be applied, it follows that the difference of potential at the terminals will be sensibly constant for a given speed, whether there be few or many lamps in action, and that these will burn with the same brilliancy whether a part or the whole of them be lighted. Further as the amount of current in circulation varies exactly with the number of lamps in action, the power absorbed by the machine rises and falls with the amount of light produced, and there is no waste of fuel at the time when the demands for current are but slight.

Although the armature shows considerable improvement in detail from the form in which it originally appeared, yet it is in the field magnet that the most striking alterations are to be seen. There are thirty-two magnets on each side alternately north and south, each north pole being confronted by a south pole, and likewise having a south pole on either side of it. The cores of the magnets are cast with the framing, which, as shown in Fig. 3, is made in halves, and then by the removal of six bolts the machine may be divided in the center, and the whole of the internal parts held open for inspection, while at the same time there is no danger of accidents from parts jarring loose and getting into the path of the armature. The magnet cores are excited by a current circulating among them through a system of copper bars. These are of rectangular section ¾ in. by ¾ in., and are bent in a special machine to a shape somewhat like that of the conductor in the armature. Supposing the cores to be numbered 1, 2, 3, &c., the first bar will pass over 1, under 2, over 3, under 4, and so on ; the second bar will pass under 1, over 2, under 3, over 4, and so on for the whole 8 bars and 32 cores, and thus each core will be completely surrounded both at its sides and ends by copper conductors. The exciting current will flow in no waste of fuel at the time when the demands for current are but slight.

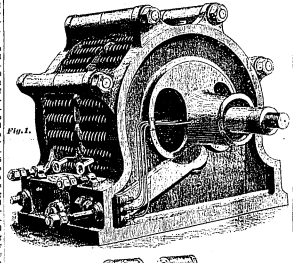

Fig. 1.

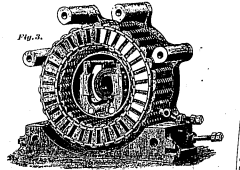

Fig. 3.

THE FERRANTI DYNAMO-ELECTRIC GENERATOR.

Although the armature shows considerable improvement in detail from the form in which it originally appeared, yet it is in the field magnet that the most striking alterations are to be seen. There are thirty-two magnets on each side alternately north and south, each north pole being confronted by a south pole, and likewise having a south pole on either side of it. The cores of the magnets are cast with the framing, which, as shown in Fig. 3, is made in halves, and then by the removal of six bolts the machine may be divided in the center, and the whole of the internal parts held open for inspection, while at the same time there is no danger of accidents from parts jarring loose and getting into the path of the armature. The magnet cores are excited by a current circulating among them through a system of copper bars. These are of rectangular section ¾ in. by ¾ in., and are bent in a special machine to a shape somewhat like that of the conductor in the armature. Supposing the cores to be numbered 1, 2, 3, &c., the first bar will pass over 1, under 2, over 3, under 4, and so on ; the second bar will pass under 1, over 2, under 3, over 4, and so on for the whole 8 bars and 32 cores, and thus each core will be completely surrounded both at its sides and ends by copper conductors. The exciting current will flow in contact. Likewise a groove is cut along each corner of the cores, and a leg of insulating material inserted into it to keep the copper and the iron apart. The current from the exciting coils at one end of the upper studs (Fig. 1), traverses one set of copper bars, is then conveyed to the other set by a connecting bar, omitted in the figure, and finally emerges at the second terminal. As the resistance of this circuit is exceedingly small, the Ferranti Company have had to construct a special exciting machine which we hope to illustrate shortly.

The mechanical details of the generator have been designed with great care. Each bearing has an oil cup of the usual form, and in addition to this three oil pipes in connection with a pump driven by the countershaft, and through these latter lubricants can be forced if the ordinary means fail to keep the bearings cool ; all the parts are made interchangeable, and the whole machine can be entirely taken to pieces in a short time. At present we are not in a position to give any account of its performances, but as we believe that no other firm, except the Telegraph Construction Company, has as yet attempted the manufacture of a machine at all commensurate with the ambitious schemes of public lighting which have been put forth, we are sure that the public will await with interest to learn how much success has attended this attempt to provide apparatus for electric light undertakers suited to the responsibilities they have undertaken.

The Electrical Transmission and Storage of Power.

By DR. C. WILLIAM SIEMENS, P. R. S., M. INST. C. E.

Amongst the numerous other applications of the electrical transmission of power, *that in electrical railways, first exhibited by Dr. Werner Siemens at the Berlin Exhibition of 1879, has created more than ordinary public interest.* In it the current produced by a dynamo machine, fixed at a convenient station and driven by a steam-engine or other motive and driven by a steam-engine or other motor, was conveyed to a dynamo placed upon the moving car, through a central rail supported upon insulating blocks of wood, the two working-rails serving to convey the two working-rails serving to convey the return current. The line was 900 yards *return current. The line was 900 yards long, of 3-feet gauge, and the moving car served to purpose of carrying twenty visitors through the Exhibition each trip. The success of this experiment soon led to the laying of the Lichterfelde line, in which laying of the Lichterfelde line, in which both rails were placed upon insulating sleepers, so that the one served for the conveyance of the current from the power station to the moving car, and the other for completing the return circuit. This line has a gauge of 2 feet 3 inches, is 2,300 yards in length, and is worked by two dynamos machines, developing an aggregate current of 6,000 Watts, equal to 12·31 H. P. It has now been in constant operation since the 16th of May, 1881, and has never failed to accomplishing its daily traffic. A line 1½ a kilometer in length, but of 1 feet 8½ inches gauge, was established at Paris in connection with the Electric Exhibition of 1881. In this case, two suspended conductors in the*

IRON.

THE EDISON-HOPKINSON DYNAMO.

A DISPLAY of electric lighting, embodying some novel features, took place last Tuesday at the works of Mr. Peter Brotherhood, in the Belvidere Road, Lambeth, and which a large number of electrical and other engineers were present. The main object of interest was an Edison dynamo machine, which has been improved by Dr. Hopkinson so that its size has been reduced, and at the same time its efficiency improved. This machine was driven direct by a Brotherhood three-cylinder engine, also of improved construction, being practically a new pattern of this type of engine. The dynamo machine, which was manufactured by Messrs. Mather & Platt, is intended for 200 Edison A lamps, or 300 Swan 100 volt lamps. The resistance of the armature equals 0·015 ohm, and that of the magnets 70 ohms. Working as shown on Tuesday the potential is 102 volts, the current external to the machine 225 amperes. The external work done equals 22,950 Watts (or volt amperes), or 30·8 horse-power. The work lost in the magnets equals 700 Watts, and the work lost in the armature 550 Watts. The commercial efficiency of the machine is 90 per cent. The total work done in driving the dynamo is 32·2 horse-power. The machine was shown both for incandescent lighting and for a single arc lamp. The improved three-cylinder engine combines all the advantages of the well-known Brotherhood engine with an economical use of steam equal to that obtained by the best types of high-pressure high-speed engines, and it runs with perfect steadiness and smoothness at very high velocities. The speed on Tuesday evening was 650 revolutions per minute, the engine being of 45 horse-power indicated. The dynamo machine was driven through a novel flexible coupling, in which leather plays an important part. This coupling is of great advantage, not only for direct driving as exhibited, but for ordinary shafting, relieving the bearings of any strain due to the shafts not being strictly in line. It consists of a ring of leathers, the outer periphery of which is held by means of a junk ring to one half coupling, the inner periphery in a similar manner to the other half coupling, the radial distances between the two half couplings being such as to allow of a very considerable amount of flexibility. Thus all friction which would arise through want of alignment in the shafting, or through unequal wear in the bearings, is avoided.

The engine and dynamo were placed in the main fitting shop at Mr. Brotherhood's works, which is about 100 feet long by 70 feet wide, and the lower portion of which was fitted up with 223 Swan and Edison incandescence lamps in equal numbers, and which were lighting the works at the same time and from the same machine. In the galleries of the fitting shop were 12 arc lamps, and in the foundry, which is about 70 feet square, were four more. These were all supplied with the current from a Siemens alternating dynamo and exciter driven direct by another Brotherhood engine. Besides these there were eleven 40-cell chloride of silver accumulators, for storing the energy generated by the engine of the Edison-Hopkinson machine, which were also in operation. These consisted firstly of a harbour light and lantern complete of the sixth order (200 m.m. internal diameter), provided with clock and screws to give the slightly-varying velocity of a double-revolution, and secondly of a masthead light, 250 m.m. internal diameter, with lantern complete. There were also shown side lights swinging in gimbals adopted to be placed in the turret now under construction on steamers. The luminous intensity of the beam from the masthead light was stated to be about 500 candles. The Edison-Hopkinson machine was shown to be instantly adapted to give a powerful search light for naval or military purposes. The carbons used are 35 m.m. diameter, and the current 200 amperes of such electrostative force between the carbons as may be desired. The reflector used in the projector was made by Messrs. Chance Brothers & Co. in accordance with suggestions from Captain Carden. Altogether the demonstration was most successful.

e had passed. The highest number 277, and the first upon the list was 272 marks. In the second year ge section, Mr. H. P. Barnet was Jr. H. Skinner in the second term, ield third in the third term. The ding and the drawing office of the r, by the results attained, the value instruction practised by Mr. J. W. nd the mode of its administration, is fortune to be ably seconded by Mr. , and his assistants. The workshop ll by the specimens of fitting and ed, is highly creditable. The colonial ch is to impart a practical knowledge work, &c. GY AND MINING.

CK SLAG.—Experiments have lately of crushing blast-furnace slag into road and railway making, &c., and a constructed by the Kingsbyian Com- to be very effective.

g Mill.—New continuous train of a great success at Dilworth, Porter ton Street, South Side, Pittsburgh, as placed in at one end, and, after it ateen rolls, emerged at the other end required but three men to attend to for a bar of iron from two inches to ple rail, requires about thirty men

ng.—At the bi-monthly meeting of Mining Institute, on Monday even- Hedley read a paper on Sonth and ing coal by caustic lime. He had seen ons at Shipley, and he minutely agent consisted of lime in cartridges d, and the experiments were made in ere was a good roof, and the seam work being done on the long wall inces under which lime was used at th from those of North Staffordshire it could not be successfully applied of the latter district, where the roofs at Shipley. Neither had they the ing Crossgill, which was a very ble bed of coal. There were other th Staffordshire, as compared with nd which would enable them to dis- vould be heartily welcomed, and he lime process fairly tried in the dis- n which followed, a general wish was w explosive should be fairly tested. place relative to the properties of d, and several recent instances of coal ained. Mr. Lawton said there was detecting such a small quantity of Abel said was dangerous when mixed rged that further experiments should be made to obtain the requisite knowledge with which to guard against the mischievous effects of fire-damp. Mr. Young said he could add as a reason of laying the dust in the most dusty seam in the district, and it answered well. Mr. Macdonald said, if salt was used for laying the dust none where the shots were fired, if any explosion occurred. his efforts were to be successful. Several other members joined in the debate.

THE NEW METHOD OF WORKING COAL.—Considerable attention is just now being taken in the mine system of getting coal by means of new catapults, which are in regular use at the Shipley Collieries, Derbyshire. In addition to the fact that trials have been made in various parts of the country with a view of testing the new method, a visit has recently been paid to the colliery by the officials of the Miners' National Union for the purpose of inspecting the system at work. Amongst those who descended the workings were Mr. Burt, M.P. (president), Mr. B. Pickard (vice-president), Mr. Crawford (secretary), &c., &c. Some of them were much impressed with what they saw, and have given notice to lay the matter before the Miners' National Conference to be held at Manchester. The notice for discussion is as follows:—"That we urge upon the House Office the necessity of finding means to test the working of coal by machinery into use the new system of getting coal with lime." When the party visited the mine, they were conducted into the workings, two yards in length, where they found a large quantity of coal had been brought down by the new process, and by reading of the above blocks. Workmen then prepared a number of holes, each 1 yard and 3 inches in depth, the time of drilling each hole did not exceed six minutes and a quarter. Four cartridges were put in each hole, and were then saturated with water, and in less than twenty seconds the coal began to crackle and was forced down in large blocks. The party were much impressed with what they had seen, and it is understood that in addition to the easy mode of getting coal, the system will be recommended, owing to it enabling miners to remove coal without having to resort to blasting or drilling, thus making it valuable in thousans which are wrought in Yorkshire and other coal-fields. It is also said to be even more economical in blasting, while the coal is brought down in much larger and more saleable blocks. A trial of the system has been made at one of the largest collieries in South Yorkshire, where the measures are inclined at a very steep angle, sudden outbursts of gas from the roof are likely, necessitating the strict use of the very best safety lamps, accompanied with strict discipline.

ELECTRICITY AND TELEGRAPHY.

THE ELECTRIC LIGHT AT SOUTH KENSINGTON.—Lieut-Colonel Festing reports that the substitution of electric lighting by the aid of two machines driven by one engine in the place of gas at the South Kensington Museum has resulted in a saving in the working expenses at the rate of nearly £70 a year, or more than £23 per annum for each lamp. Up to the end of last year the thirty-two lamps illuminating the Lord President's Court and the Sheepshanks and Raphael Galleries had been at work for nearly six months, or 1,365 hours of lighting. The second 16-light Brush machine was brought into operation in May.

SUBMARINE TELEPHONES.—From the report which has been addressed to the National Telephone Company on the recent experiments at Dover with a view to establish telephonic communication between vessels and the shore, it appears that the operations have been attended with complete success. In spite of rough weather, the cables were finally laid, and various persons and offices in the town of Dover were placed in communication with a vessel anchored at the Admiralty Pier, and subsequently with the Marine Christine Club. The conversation, it is stated, was very distinctly maintained, whether by the aid of an Allen or a Cooper apparatus. Some time later the wind gained strength and the vessel rolled considerably; but the voices of the parties in communication were nevertheless distinctly heard. This new application of telephony is expected to render important services to maritime commerce, since it will allow vessels arriving off a port to place themselves immediately in direct communication with their owners or agents ashore.

ELECTRIC RAILWAYS.—The development of electric railways and tramways is now considerable. Putting aside numerous lines that are merely in course of construction, there are now in actual work, or in course of construction, about a total length according to the *Revue Industrielle*, July 19, of more than 160 kilometres (about 100 miles), and grants are becoming even more numerous. The lines actually at work are those of Lichterfelde (about 2½ kilometres in length), and that from the Spandauer Bock to Charlottenburg, near Berlin; another line, from Port Rush to Bush Mills, in the north of Ireland, has been inaugurated (length about 10 kilometres), and also in Holland, one from Zandvoort to Kostverloren (length a little over 2 kilometres). Among lines authorised or in construction, the following are noted.—In Austria, the Mondling line, near Vienna (2½ kilometres), to be constructed by the Southern Railway Company there. In Germany, the line from Wiesbaden to Nerobergs (4 kilometres), and that from the top to the bottom of a quarry at Cudenbach, in Silesia. Where there is a fall of water, as at Leading Crossgill, the Lichterfelde Stations (1·2 kilometres), also a line in South Wales (60 kilometres), for which the force will be derived from fall of water. In Italy, Turin and Milan will soon begin the construction of electric tramways. In America, the Edison Company have arranged for the working of 80 kilometres on one of the great lines from New York. Another small line (1·8 kilometres) is to be made at St. Louis, in Missouri, by Mr. Heslet.

ELECTRICITY AND EVAPORATION.—Experiments very recently made by Mr. Lemstrom have thrown an important source of atmospheric electricity. Experiments, however, hitherto yielded little evidence of this. Thinking further inquiry desirable, Mr. Freeman, of the Johns Hopkins University, Baltimore, lately experimented thus. A copper or tin

IRON.

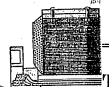
No. 550.

LONDON, FRIDAY, MARCH 9, 1883.

THE ELPHINSTONE-VINCENT DYNAMO-ELECTRIC MACHINE.

In the year 1879, Lord Elphinstone and Mr. C. W. Vincent, F.R.S., commenced a series of researches and investigations with respect to dynamo-electric machines, the results of their labours having been from time to time communicated to the Royal Society. The practical outcome of their joint labours is the continuous current dynamo-electric machine which we illustrate on page 186 of our present issue. In our engraving, fig. 1 represents a longitudinal and fig. 2 a transverse section of the apparatus, fig. 3 being a general perspective view. In these machines a very cylindrical drum upon which the armature coils are laid longitudinally rotates between the poles of an exterior and interior magnet; each coil is made some what in the shape of the frame of a saddle. They are removable, and a faulty one can be replaced in a short time. The armature consists of eighteen of these coils. The separate magnetic circuits enable the inventors to have a low resistance, although comparatively thin wire is used. There is no iron in the armature, consequently there is no magnetisation and demagnetisation, and Lord Elphinstone and Mr. Vincent maintain that this is the most efficient system upon which to construct dynamo machines. It is stated that an electrical efficiency of 82% to 84% or 91 per cent. can be obtained, according to whether it is desired to attain the best return per horse-power used or maximum current without considering horse-power; and this change of efficiency can be effected in a few seconds. With from 240 to 320 ampères of current—*i.e.*, enough to light more than 400 Swan lamps—the armature is barely warmed. It is stated that a machine on this system can be built of a size to light a whole town, supce the parts are capable of almost indefinite multiplication. The great object of the inventors has been to provide the current for a large number of lights without multiplying the number of the machines, shafting, and belting. As the coils and magnets are wound apart from the machine, they can be always attained by many of his successors in the ranks of inventors, yet it amply illustrates the value of diligent and patient application and perseverance, qualities which, as they are at the foundation of this country's greatness as an industrial nation, we would fain hope are as ever present with our workers now as in the past. How these qualities were employed and led to early and deserved success in the case of Nasmyth, could not be told in a more graphic and straightforward manner than by the pages before us from his own pen.

James Nasmyth was born at Edinburgh in 1808, and came of a gifted family. He early manifested a very decided taste for mechanical pursuits, and was fond of frequenting the workshop of his father, for though the latter was by profession an artist and architect, his chief relaxation was found amongst his tools and tools. The son's natural bent took a ractical turn at an early age, and he drove a small rade among his schoolmates in the spinning-tops and ninature cannon which he was able to turn out in a father's workshop. Amongst his school companions were two of a similar disposition to his own, and in the foundry belonging to the father of one, the latter



JAMES NASMYTH.

THE inventor of the steam hammer has been conspicuously the right man in the right place. James Nasmyth was the child of the era inaugurated by the opening of the Liverpool and Manchester Railway in September 1830, and he was the parent of many of the inventions which have contributed to the wonderful progress made in the mechanical arts during the past fifty years. With the adoption of railway locomotion, and the rapid development of steam navigation, it was found that the method and appliances which had done duty up till then were not adequate to the demand upon them. There was a call for machine-making tools of increased power and precision, and on more than one occasion Nasmyth proved his possession of an admirable resource by the ready response with which he met the want. We should not be doing justice, however, to his foresight if we omitted to mention at the same time how often he had paved the way, by the invention of some simple but ingenious contrivance, for the realisation of the perfection to which machinery has been brought nowadays. If his life does not present a record of fierce battling with difficulty and failure, such as has so often been the only road by which success has been attained by many of his successors in the ranks of

THE ELPHINSTONE-VINCENT DYNAMO-ELECTRIC MACHINE.

In the year 1879, Lord Elphinstone and Mr. C. W. Vincent, F.R.S., commenced a series of researches and investigations with respect to dynamo-electric machines, the results of their labours having been from time to time communicated to the Royal Society. The practical outcome of their joint labours is the continuous current dynamo-electric machine which we illustrate on page 186 of our present issue. In our engraving, fig. 1 represents a longitudinal and fig. 2 a transverse section of the apparatus, fig. 3 being a general perspective view. In these machines a very cylindrical drum upon which the armature coils are laid longitudinally rotates between the poles of an exterior and interior magnet; each coil is made some what in the shape of the frame of a saddle. They are removable, and a faulty one can be replaced in a short time. The armature consists of eighteen of these coils. The separate magnetic circuits enable the inventors to have a low resistance, although comparatively thin wire is used. There is no iron in the armature, consequently there is no magnetisation and demagnetisation, and Lord Elphinstone and Mr. Vincent maintain that this is the most efficient system upon which to construct dynamo machines. It is stated that an electrical efficiency of 82% to 84% or 91 per cent. can be obtained, according to whether it is desired to attain the best return per horse-power used or maximum current without considering horse-power; and this change of efficiency can be effected in a few seconds. With from 240 to 320 ampères of current—*i.e.*, enough to light more than 400 Swan lamps—the armature is barely warmed. It is stated that a machine on this system can be built of a size to light a whole town, supce the parts are capable of almost indefinite multiplication. The great object of the inventors has been to provide the current for a large number of lights without multiplying the number of the machines, shafting, and belting. As the coils and magnets are wound apart from the machine, they can be always

steel being fused. The current was then made to run through a coil of iron wire immersed in a glass vessel holding three quarts of water; instantly there was a flame as when a red-hot poker is plunged into water. This was followed almost immediately by steam; in half-a-minute the water boiled, and before a minute had elapsed half the contents of the vessel was on the floor. An ordinary steel flat file 1 inch by 1 inch was then placed instead of one of the carbons in an arc light, and the current being passed through, the end of the file was melted and consumed like a tallow candle in a fire, throwing off a shower of sparks. The experiments concluded by the lighting up of a very powerful search light, as used by the navy, the carbons of which are 12 inch in diameter, capable of giving a light said to be equal to 100,000 candles, and which made a very brilliant display. The mechanical arrangements were carried out by Mr. Arthur Rigg, C.E. The motive power used for driving the dynamo machine is supplied by one of Rigg's high-speed engines, capable of developing 60 indicated horse-power. In conclusion, we have only to congratulate Lord Elphinstone and Mr. Vincent on the marked success of their efforts to produce a cheap, simple, and highly efficient machine, and to state that the temporary offices for these dynamos is at No. 78, Gracechurch Street, London.

Engineering, Dec. 29th 1882.

THE SPEED AND RESISTANCE OF DYNAMOS.

It is well known that the internal resistance of magneto and dynamo-electric machines increases with the speed at which they are worked; if the recent experiments of M. E. Lecoine are correct, this effect is mainly, if not entirely, due to the increased resistance between the rubbers or brushes and the commutator. These brushes rubbing on the slips of the commutator are, in fact, so many microphones, and their resistance varies with the speed of rotation and the pressure of the rubbers on the slips. According to M. Lecoine's experiments made at Montmirail, the resistance of a circuit comprising a battery, a telephone, a galvanometer, and a commutator made after the model of the Gramme machine one, was when at rest only 08 ohms; at a speed of 2000 turns per minute it rose to 180 ohms; at 3000 turns, to 900 ohms; at 5000 turns, to 1507 ohms; and at a very great but unmeasured speed it reached the enormous value of 2993 ohms. In these experiments each spring or rubber touched three slips at once; of course in making a touch more than three the effect was less appreciable but still great. For a given speed the resistance decreased when the pressure of the springs was increased; and it is possible to arrive at a pressure which will suppress the microphonic effect and produce silence in the telephone joined up in circuit. Measurements taken by M. Lecoine led him to infer that the increase of resistance is proportional to the cube of the speed.

Occasional Notes.

THE MANUFACTURE OF CAST-IRON PIPES IN FRANCE.

In France the founders of Torteron in 1822 and of Maruejols in 1841 first put down plant for casting pipes horizontally. In 1847 the engineers of the Paris municipality required that all pipes over 400 millimetres (4 inches) in diameter should be cast vertically, which led to the Torteron foundry being the first to produce them. In 1848 the Maruejols works followed suit, and until the year 1862 these two establishments had the monopoly of making cast-iron pipes in France. In 1860 the firm now incorporated with the Société anonyme des Chementery-Four chenbusch obtained a patent for an improvement in the manufacture, whereby a greater quantity of pipes per day was obtained; but it was only put into practical operation in 1861-2.

By their patent of March 1, 1861, they claimed the manufacture of pipes in vertical foundry boxes, invariably fixed, the moulds being dried in place by natural or gaseous fuel. A little later MM. Pinart Frères, of Marquise, renewed their plant according to the process of Messrs. Walker & Stewart, patented in England a few years previously. This process was not followed at any other works; but, on the contrary, all founders tried to imitate the Torteron method. The next patents secured in France were those of MM. de la Rochette & Cie. in 1862, the Terre-Noire Company in 1868, and of M. Dard in 1868-9. In these systems the pipes are cast vertically, and the box is fixed, though movable laterally, ideally and round a vertical axis. Another method, patented by MM. Hubly-Rochling & Cie. differs from that of Torteron in that the upper instead of the lower box being lowered. To these methods must be added in France the casting pipes inside themselves into two—(1) the English system of compressing the sand mechanically and moving the boxes on a track, as practised at the Marquise works; and (2) the Scotch system with boxes attached to a fixed or movable frame, as practised at Torteron, La Voulte, Fourchambault, Mans, Aubrives, Pont-à-Mousson, and Montluçon.

THE DISTRICT RAILWAY VENTILATION.

Extensive steps are being taken with a view of conveying the Metropolitan District Railway Company that they cannot with impunity defy the public opinion in being organised, on a scale which cannot but be despised even by a powerful railway company, in the form of somewhat modified plans before the House of Commons. Mr. Fowler, the late mayor of a northern town, and Mr. Lockwood, has given "After second reading of the Metropolitan and District Railway (City Lines and Extensions) Bill, to move, That it is referred that they have power to insert in the said bill a clause making it compulsory upon the said companies to pull down the ventilators now erected, or in course of erection, in Tothill Street, Broad Sanctuary, Victoria Street, the Thames Embankment and Garden, and in Queen Victoria Street, under the Mansion House and Cannon Street Railway Stations, and to reinstate the said ground in such terms as may seem reasonable to the committee." This opposition is seconded both by the Corporation of London and the Metropolitan Board of Works, the Court of Common Council, and the Metropolitan Improvement Committee to draw up a clause for insertion in the Lunac Circular Company's Bill, which have declared a petition in the Private Bill Office of the House of Commons, praying that the Standard Office of the House may be dispensed with in the case that a bill may be introduced for the repeal of the clauses under which the Metropolitan District Railway Company are empowered to erect ventilators on the Thames Embankment and other parts of the neighbourhood. It would be very strange indeed if the railway company were able to resist such combined pressure.

THE NEW BANKRUPTCY BILL.

Mr. CHAMBERLAIN was able, on Monday evening, to move the second reading of his bill in the House of Commons. In introducing the measure, he described the cardinal principle of the bill to be that it would secure for every case an independent and impartial examination. The person best able to do this duty of cross-examiner. The powers entrusted to the official receiver under the new bill would be very extensive. He would be the person to whom the debtor would have to make his statement of affairs, and he would have the power to investigate the conduct of the bankrupt and the causes which have led to the bankruptcy, to conduct the public examination of a debtor before the court, and, if necessary, to report to it any misconduct on the part of the debtor's affairs, and any misconduct on the part of the bankrupt which has been disclosed in the course of the proceedings. This officer will be subject to the control of the Board of Trade. The other main object of the bill is to provide for the honest and economical administration of bankrupts' estates. The criticisms presumed upon the measure on its second reading cannot be said to be very hostile to its general principles. On the whole, the House was in its favour, as there is much good in the bill, and it is a decided reform in our bankruptcy law.

PRIVATE BILL LEGISLATION.

In the speech with which Mr. Sclater introduced his motion for the above subject to the House of Commons there appears to be evidence of a somewhat important character. We allude to the effect which the existing system exerts upon the trade and manufactures, and, we may also add, upon the agriculture of this country. It has been computed by competent persons that, if the lines owned by the various great English railway companies could have been constructed on the Prussian system, *i.e.* without the usual preliminary and parliamentary expenses, each of those companies would be able to carry traffic at a reduction of 25 per cent. upon the prices at present charged, without adversely affecting the market value of their stock, or diminishing in any way the dividends which their shareholders are now receiving. What the effect of such a reduction in traffic rates would have upon the manufacturing interests of the country, at the present moment, it is needless for us to point out. It is a matter of common knowledge that the migration of Messrs. Cammell's steelworks from Dronfield to the coast has been occasioned solely by the high railway carriage of fuel and raw material and the manufactured products; and there are scores of other industries in addition to the rest of the kingdom which, from the same cause, added to the fierce foreign competition to which they are now subjected, will be compelled altogether to close their works. If, on the same principle, the carriage of the ordinary mails were delivered, in a greater or less degree, the charges of all gas and water companies, and in every case is in the public who suffer.

THE AFRICAN INLAND SEA.

A party of explorers, under the guidance of M. Fernand de Lesseps, has left Tunis for Gafsa. Of course it is supposed to proceed on horseback across the desert lying between that town and the great marsh lakes of Southern Tunis. M. de Lesseps is very sanguine as to the results and details of the inland sea scheme. The proposed basin will be fifteen times as large as the lake of Geneva. The excavations engendered in its course will be of time-to-time extracted by the fact of four batteries, consumed with 1,000 foot-pounds) of work per second, producing 1 kilogrammetres of water per minute, pre-heating 1 kilogrammetres per minute, pre-heating 1 kilogrammetres per minute, pre-heating 1 kilogrammetres

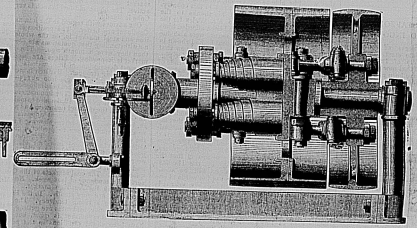

FIG. 1. [CUT 7]

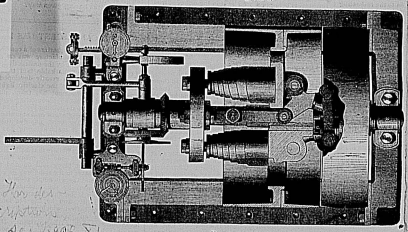

FIG. 2.

IRON. June 16, 1882.

BOURRY'S DYNAMOMETRIC GOVERNOR.

THE great increase in the adoption of electrical illumination opens up a new field for this governor, which variations of the resistance. The first two instruments are is claimed to be the only one, really practical, that can be easily distinguished in the illustrations. As regards the of employing the electric light in many works where power is not constant. Hitherto, the plece of the pencil only is shown at the end of is not always in excess of power available. By its aid the the rack of the dynamometric index, the arrangement of the power is automatically distributed among two or more lamps, and the number of these can be increased or diminished according to requirements, while still thus serve as accumulators of figures. An ordinary counter is shown in the last two lines of this governor also renders it especially useful in exactly with that of the steam-valves of the engine; these valves almost momentary, as well as in connection with positions of the slider, which may be obtained empirically, the engine engines. Instead of depending upon variations or better still by calculation. It is not necessary that all from the normal speed, the increase or M. A. Bourry, of Saint- these instruments should work constantly. They, in alternate by the tendency of centrifugal force on the shaft, and also the fact that in the same way as an indicator. On the this shaft is subjected to a rotatory force at one end and to a screw engine, there is every reason to cause the work of substance at the other. At a rule, this shaft is under strain, the engine and the resistance of the propeller to be broken utilisable; but, in order to make it serve for the desired record of the state of the sea. It is always useful to be purpose, it must be increased artificially, by concentrating the dynamometric counter to work continuously, whatever be the load. This point by means of springs judiciously applied. The nature of the motive to which it is applied, it will indicate in the mode in which is reflected, as it were, the resistance the power given out from any given instant, and will opposed to the engine. The arrangement adopted by M. permit of comparing the effective force developed with the Bourry consists in converting all circular strain into quantity, at the moment of observation, and, therefore, in case of rectilineal pressure, which permits of applying the greatest checking of the amount of motive power let on blow, this number of the best springs known. These are placed round instrument is always indispensable. The dynamometric and near to the shaft, and, as this offers great advantages indeed, when given a constant indication of the resistance, as regards distribution of the strain, facility of installation, and consequently the strain is not constant, but, on the contrary, there are quite a host of claimants for the engine-man and stoker, enabling them to with a perfect governor, which may be set, to small limits, record the measure of the work done in any powers as well as the largest engines, such as those of screw- establishment, while an exact reproduction of the indications steamers, because it consumes no part, without sensible can be obtained at any moment. This governor, in the office, which, moreover, is applicable to all cases where regulation is required.

The engravings on pages 564 and 565, for which we are indebted to M. Dingler's Polytechnisches Journal, show two types of this governor, the first, for Belgium, may possibly exist, and the second, applicable to all cases where elevation at fig. 1 and in plan at fig. 2, the appliance is mounted on a special bed-plate, which may be attached to the floor, to a wall, or to the engine. An intermediate shaft is interposed between the motive-shaft and the driven shaft, and carries two pulleys, one of which is fixed, and the other, on the left from the engine, while the screw and loose, receives for allowing of the manipulation of the latter. The fixed pulley is driven by the motive-shaft, by means of a belt, and receives its motion from the first by means of a belt, and coupling; under certain cases, the two pulleys may be replaced by grooved wheels.

The second arrangement, shown in elevation at fig. 3, and in plan at fig. 4, places the appliance connecting the lay shaft with that of the engine in the case of screw steamers. In both arrangements, according to circumstances, by compression, by the engine is put in motion, the and it afterwards transmitted to the slider and the spring, slider, by the position of which, according to the load on the engine, is always corresponds exactly with ment to the steam-valves, the slider is provided with a collar which participates in its reciprocating but not in its rotary motion. This governor, resembling the whole power given out by the engine, acts as a constant dynamometer, which may be fitted the various arrangements, to which reference of which are derived from that of the collar on the slider.

The first of these instruments, the dynamometer proper, serves to measure the resistance opposed to the engine; it consists of a graduated dial, on which works a pointer; it carries its motion from a rack attaining a small pinion, to become a counter, recording with greater or less speed according to the resistance to be overcome by the engine, which resistance it records in kilogrammetres or foot-pounds.

thus constituting a dynamometric indicator analogous to gas and water meters. A third instrument, the "dynamograph," represents graphically, on an endless band of paper, the

For Illustrations see previous & page of

In order that this appliance may work with precision as governor, its action must be regulated so as to correspond

THE TELEPHONE PATENTS IN AMERICA.

THE labours of Prof. S. P. Thompson to put on a proper footing the work done by Philip Reis towards the perfecting of the telephone, as we know it, have little room to doubt that the Friedrichsdorf schoolmaster need be recalled in future with the honour of being the inventor of the telephone; but Reis was only a teacher of natural sciences at a school in a small Germam town, and probably had not the means to push his invention into the notice of capitalists, even if he was in a position to demonstrate its capabilities to them in such a way as to induce them to furnish him with the means of patenting his device. So far as we know, the very word "telephone" was Reis's invention, and there can be no doubt that the publication of his paper in

the *Sitzenberichte des Physikalischen Vereins zu Frankfort-am-Main* for the session 1860-61, gave just the information that inventors and investigators would be likely to take hold of, and turn to account in the commercial world, and also in the domains of science. It must be confessed that, with the exception of Varley, Barlow, and perhaps one or two others, very little had been done in this country by inventors or men of science on the line which led Bell to success, although in all probability Reis himself derived the initial idea from some observations in the works of Dr. Robert Hooke, and of Dr. Robert Willis. On the contrary, there are quite a host of claimants for some parts of the telephone, and as their claims are supported [and limited] by documentary evidence, there is no doubt of their bond-fide character so far as the evidence carries them. So far back as March, 1878, the first of the "interferences," as they are called, was declared, and the United States Patent Office has ever since been engaged in deciding between and amongst the rival claimants. The interferences originally involved in the first "interference" were Bell, Berliner, Blake, Channing, Dolbear, Edison, Gray, Holcombe, Irwin, McDonough, Phelps, Rhoades, Truesdell, and subsequently Pollard. There are other claimants, but their cases have not yet been decided. Six of the above-mentioned persons were disposed of, as far as the first interference is concerned, some time ago, and the examiner-in-chief appointed by the United States has now given his decision as regards the claims of Bell and Dolbear, which decision practically leaves the whole dispute between these two. In order to settle the rival claimants—that is, those who are left with anything—an arrangement between Edison, Gray, Holcombe, Irwin, Pollard, and Dolbear did not avail those devices prior to Bell's patent, and consequently awarded priority to the last named.

The subject matter of the interference between Bell and Dolbear is so important of all, for the invention is described and fitted as a telephone receiver, consisting of the combination in an electric circuit of a magnet, and a diaphragm, and so arranged in close proximity thereto, whereby sounds thrown upon the line may be reproduced accurately as to pitch and quality. The invention is awarded to James W. McDonough, of Chicago, and May, 1873, is fixed as the date of the invention. Three other cases were awarded in favour of Bell, and another—Channing—lost on the spring forming or carrying one electrode and constantly pressing against the other and the diaphragm—to Edison. It seems that no day of the month is assigned to McDonough's invention, nor is it gathered from the following:—It appears that in December, 1867, McDonough invented and constructed a telephone and on the 20th of August, 1871, he made a drawing of a diaphragm telephone-call receiver, with its circuit and the battery; and early in May, 1873, he constructed and practically operated, a telephone, by means of the human voice and an electric current through wires connecting a diaphragm transmitter with a diaphragm receiver. On the 10th day of April, 1876, he filed application for a patent claiming the reproduction of articulate speech, and, subsequently, he was awarded a "telephone." It was not until Jan. 15, 1877, that Bell described such an instrument; but thanks to the arrangements connected with the examination department of the United States Patent Office, a patent was issued to Bell fifteen days after McDonough's invention had been available by issue of the patent for nine months. It will be seen by carefully reading the descriptions of the inventions above given, that the question of the telephone patent is a very peculiar position. Indeed: for the examiner has granted McDonough's claim to be the inventor of what is commonly known and used as the Bell receiver, or, in fact, of any receiver combining a magnet with a diaphragm. But inasmuch as the examiner has granted Bell's claim to be the inventor of the art of transmitting and reproducing at a distance sonorous waves or vibrations by increasing or decreasing the strength of an electric current, he has practically awarded to Bell a monopoly of all conceivable systems of telephonic transmission by electric means, although it is clear that as McDonough made a receiver and used it before Bell, he must himself have been the inventor or the discoverer of the "art." As if this complication were not sufficient to puzzle the historian of invention and the defenders of the American system of examination of patents, there is a possibility, some say a probability, that all the decisions given will be so much waste paper if Jenkins' Lenin tissue, for which Mr. Dewhurst has entered claims which, if they are upheld by evidence, will destroy those of McDonough, who certainly did invent a speaking telephone before Bell. In one sense it may be hoped that Dewhurst will establish his right to the title of inventor of the modern speaking telephone, for such a result will probably facilitate arrangements with the holders of the present patents and prevent innumerable appeals to the law courts. The result of the recent inquiry was to show that the United States patent system is in a most confused state, and it would appear as if arrangements for the examination into the novelty of inventions are likely to become drawn very badly when tested by a really complicated case, and should certainly not be copied by this country or any other which really desires to promote invention. One other point may be noted in connection with the above cases, and that is the fact that several contemporary inventors equally deserving of honour.

THE DYNAMO: HOW MADE AND USED.—II.*

By Silvanus P. Thompson.

NUMEROUS inquiries have appeared in "notes" respecting the construction of dynamo-electric machines, and replies equally numerous have been forthcoming. But except to those who have turned their hands to the construction of small dynamos, appear to have little comprehension of the principles on which it is intended to put the dynamo when constructed.

In the following papers, I shall confine myself strictly to the latter purpose, as being more within the reach of our amateurs, whether students of science or of the practical arts, who are engaged in repairing steam or other engines to act as motive power.

I. *What a Dynamo is and how it is used.*—At present, the dynamo-electric machine may be described as a machine whereby energy received is converted into electricity by the aid of the rotation of magnetic power in certain two portions: which electricity is caused to react on the iron and so heighten its magnetism; and this increased magnetism in its turn gives rise in the conductors to greater effects, and so, until a limit is reached, dependent partly on the capacity of the machine, partly on the speed and experimentum of the size and quantity of the wire and iron employed in its construction, and partly on the resistance throughout the circuit. Although this principle was fully understood, and

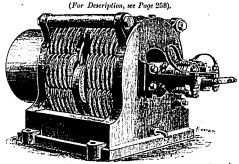
THE FERRANTI CONTINUOUS CURRENT GENERATOR.

(For Description, see Page 258).



THE FERRANTI CONTINUOUS CURRENT GENERATOR.

THE Ferranti generator is of the alternate current type, and avoids a separate alternate-current machine to excite its field magnets. In the past the Ferranti Company, while concentrating their attention upon improving the details and lessening the cost of construction of their machines, have been content to buy their armatures from other makers. Lately, however, for reasons which will appear, they have turned their attention to the problem of obtaining continuous currents from their machines, and have attained very satisfactory results. On page 12 last we gave illustrations of a Ferranti generator designed to feed 5000 incandescent lamps. The most striking novelty in its construction was in the use of simmers bars of copper wound in and out below the field magnet cores as the conductor for the exciting current. These had an almost insignificant resistance, and therefore it followed that the exciting machine which furnished the current reversing the lamps would also have a small internal resistance, and be capable of generating a current of great intensity and small electromotive force. Except for the purpose of electroplating, such machines do not exist, and hence it was necessary for the Ferranti Company to bring out a new pattern suited to their requirements, and they determined to adopt a design which had been successful in their hands for the generation of alternate currents, adding to it a commutator for the purpose of turning the vibrations into the same direction. By the kindness of the owners of the machine we may before our readers not only a perspective view of the machine, but also a complete set of working drawings, from which it will be seen that very good care and thought have been expended over the details of construction, and that no pains have been spared to make it possible in the way of providing ample bearing area and efficient means of lubrication to insure that the original conception shall not suffer from being carried out under unsatisfactory mechanical conditions. It has been our lot at different times in the past to see many electrical experiments fail, and much wrong and unnecessary expense in their promoters by faults of construction which might have been avoided if the electrician had been sufficiently trained to accept the assistance of a mechanical engineer, and we fail with satisfaction file evidence that the electrical companies are awaking to the fact that a dynamo machine must not only be capable of generating a current, but also of running continuously without hitch or trouble.

The general design is that of a Ferranti machine having five inwardly-projecting armatures in the armature, and ten field magnets, or a multiple arc of 5. The magnet cores are cast with flat faces and are wrapped with copper strips 11 in. wide by 3/16 in. thick bent edgeways so that they pass in a zig-zag fashion backwards and forwards between the ends of each strip passing not round and round one particular core as is usual in the conductors of electro-magnets, but under one, over the next, under the succeeding one, and so on. The silver plate strips are applied to break joint, as it were, and thus each core is completely surrounded with conductors not only at the sides but also at the top and bottom. The magnet poles are alternately of opposite polarity, the current flowing in one direction between any two cores producing a north pole in the right-hand core, and a south pole in the left-hand core, the connexions between the strips being so arranged that the currents in them all tend to produce the same effect on a given core. The strips are insulated from one another and from the iron cores by pieces of vulcanised fibre, and after they have been laid in their places, are secured by two brass bands (Fig. 1, page 258), one encircling the outer periphery of all the cores and one being within them. The resulting current enters the one terminal (Fig. 3), traverses the strips on one set of magnets, is then led by a copper connecting piece (Fig. 4) to the other strips, and thence to the second terminal.

The armature consists of a boss having five double arms (Figs. 1 and 2), carrying four copper strips 12 in. wide by two millimetres thick, bent into a sinuous form somewhat resembling the outline of a wheel with five blunt pointed teeth. Each strip makes two complete coures round the armature, and is connected at either end to an insulated conductor passing through the main spindle (Fig. 5). The whole of the strips is fixed to the boss by thimble-rivets (Fig. 1).

Coming now to the commutator it will be seen that it differs in construction entirely from any previous device for the same purpose. The rubbing surfaces are not set around the circumference of the commutator as is usual, but at its end, and they move in contact with solid conducting pieces in place of brushes. There are ten fixed collecting pieces arranged in a circle, and insulated alternately to the three and negative leads, and there are six moving contact pieces sliding over them, the latter joined to one terminal of the armature, and three to the others. At a given moment when a current is being generated in the armature in one direction, three moving contact pieces connected to one end of it, stand opposite three of the fixed collecting pieces which are in communication with (say) the positive lead, and the contact pieces in connexion with the other end are similarly in communication with the negative lead. When the armature has rotated through the current in its conductor becomes opposite to that just imagined, and at the same time the three contact pieces which were touching their collecting pieces become transferred to the negative collecting pieces and *vice versâ*. Between the two instants when the current is flowing one way or the other in the armature, there is a moment of rest or neutrality, and at that time the contact pieces are passing over insulated strips interposed between the positive and negative collecting pieces.

A general appearance of the commutator is to be seen in our perspective view on page 250, while Fig. 9 is a plan of it. The main spindle is hollow for a portion of its length, and within it there are placed two insulated conductors P, P (Figs. 5 and 10), one connected to each end of the armature. Two insulated terminals are screwed into the conductors (Figs. 10 and 16), and convey the current to two insulated half discs B B (Fig. 17) fixed to the end of the spindle. Upon these half discs there are six raised contact pieces, 1 to 6, the odd numbers being connected to one pole and the even numbers to the other. Opposite the half discs there is mounted a stationary plate A (Figs. 5, 8, and 11) in whose face there are 15 sector strips, a, a_1, a_2, of which five are connected to the positive terminal and five to the negative terminal, and five are insulated. These marked a form part of the front plate A, which is a ring with five degree pockets inwardly towards the centre; those marked a_1 form part of the thrust plate A1, while those marked a_2 (Figs. 10, 11, and 12) are separate blocks fixed by their flanges to the face of material between the plates A and A1 (A to be insulated (Figs. 5 and 9), while a second bundle joins the plate A1 to the second terminal (Fig. 9). There is worm G and a worm segment D (Fig. 6), by which the collectors can be set to the place for sparking.

A moment's reflection will show that if the disc B, be applied to A in such a position that the contact pieces 1 (Fig. 17) coincides with a sector in (Fig. 11), then the pieces 3 and 5 will also coincide with two other sectors a, and the pieces 2, 4, and 6 will coincide with three of the sectors a_1. At such a time the two radial portions of the armature will be generating, and the poles of the magnetic field and the current will be at its maximum. From this point a rotation of 10 deg. will carry the armature bars into the neutral spaces between the poles, and during this position the current will have fallen from its maximum to zero, and at the same time all the pieces 1 to 6 will have been transferred from the sectors a and b to the insulated sector c, and thus all communication between the armature and the external circuit will be cut off. Another 5 deg. of rotation exactly reverses the first conditions, but as the current is now flowing in the opposite direction in the armature, it follows that it maintains its old course in the external circuit, while the positive collecting pieces come with each rapidity that they form practically a continuous current. The machine is intended to run from 300 to 400 revolutions per minute, and at that speed gives a current of 500 amperes with an electromotive force of 10 volts.

Engineering, Feb. 1883.

THE DYNAMO MACHINE AND ROLLING STOCK.

The electric locomotive of Dr. Siemens will doubtless be useful in many ways, and prove a good auxiliary to the steam locomotive, but it will be very long, if ever, before it supersedes the latter for general traffic. There is, however, some value in the suggestion of Lieutenant Cardew to use the dynamo-electric machine in conjunction with the steam locomotive in order to communicate the power of the latter to the wheels of the carriages in a train, without having to resort to the wasteful "grip" or friction of the driving wheels upon the rails. Moreover it could be made to apply the brakes to the carriage wheels in stopping the trains. Lieutenant Cardew's plan is to have a dynamo machine on the locomotive and each carriage, the revolving armatures being mounted on the axles of the wheels, and all connected up together in such a manner that the current generated in the armature of the locomotive machine by the revolution of its driving wheel would circulate through the magnets of all the other machines, turning round their armatures, and consequently also the carriage wheels. When it was desired to stop the train, the engine driver and guard, by means of two switches, under their respective control, would change the direction of the current and reverse the motion of the armatures on the axles of the wheels, thus tending to bring the latter to a stop. The check would be strongest at first, and gradually less, but this is in accordance with Captain Galton's finding that a brake should apply a powerful force to begin with for a short time, followed by a gradually diminishing one in order to prevent the skidding of the wheels which takes place if a strong pressure is kept upon them while they slacken. At first sight it might seem against Lieutenant Cardew's plan that the wire connexions to be made would prove very inconvenient in practice where trains are made up of different carriages; but this drawback could be overcome by properly designed contact pieces. With regard to the efficiency of the dynamo-electric machine for transmitting power, Mr. Mansell has shown it to be a half when it is giving out work most *readily*, and Professor Ayrton has proved it to be as much as three-fourths when giving out work most *economically*.

ELECTRO-MOTIVE FORCE OF THE BRUSH DYNAMO-ELECTRIC MACHINE.*

PROFESSOR HENRY MORTON.

Some recent experiments, which I made in determining the electro-motive force of the Brush dynamo-electric machine, and various instruments for the accurate measurement of electric currents of great strength, show that each pair of coils on the armature of the machine develops a fluctuating electro-motive force, the projection of which gives a kind of oval curve around the centre of a diagram.

When the ends of the main pair of coils are considered, it is found, that they show a kind of eight-lobed

* Read before the National Academy of Sciences, N. Y., 1880.

figure with intersecting lines in certain places. These intersections, if compared with the positions of the commutator, are found to coincide exactly with the points at which rupture of circuit occurs, and thus show that each pair of coils is thrown out, not at the point where its force is least, but at that at which its electro-motive force is equal to that from which it breaks; thus suppressing a spark, but only at a certain sacrifice of theoretical efficiency.

EDISON DYNAMO-ELECTRIC GENERATORS FOR ISOLATED PLANTS.

(For Description, see opposite Page).

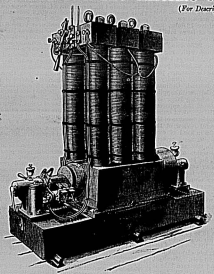


FIG. 1. 250-LIGHT (S) DYNAMO.

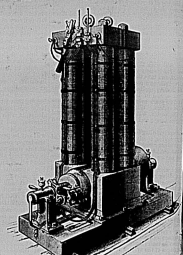

FIG. 2. 100-LIGHT (L) DYNAMO.

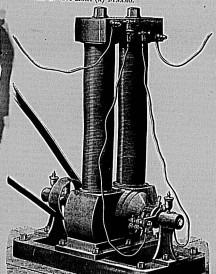

FIG. 3. 50-LIGHT (J) DYNAMO.

EDISON DYNAMO MACHINES.

LAST week we published an engraving of the 1200 light dynamo machine employed by the Edison Company in central stations, and now we give on the opposite page three other illustrations showing smaller machines designed for private lighting. These are designated by the makers as L, J, and Z machines, and are intended to feed 100, 50, and 40 lamps respectively. The general characteristics of the three machines are very similar; in each suitable drawing, spun from their axis, lying in the number of field magnets employed, which varies from six examples before us from two to six. In every case the field magnets is mounted upon the crossbar of the electro-magnets are stationary and the armature alone revolves; and to follow the principle of the earliest machines designed thirty years since by Professor Holmes for lighthouse use, in which the magnets were ranged round the periphery of a large revolving wheel. In the so-called new machine of Mr. Gordon the wheel is 8ft. 9 in. diameter, weighs 7 tons, and revolves at a speed of 140 revolutions per minute. This gives a point in the rim of the wheel a velocity of rather more than 60 feet per second, or 1200 yards per minute—a very fair rate for an express locomotive. The machine is driven by an engine indicating 150-horse power; but there is another smaller engine employed to drive the subsidiary Jürgen machines, which, running at 800 revolutions per minute are required to excite the magnets of the large dynamos. It should be stated that the total weight of the large machine is 18 tons, and it stands on a bed-plate measuring 19 ft. 4 in. by 7 ft. Great advantages are claimed by this return to the Holmes type of machine; but it may be remembered that equal benefits were supposed to be obtained when the armature was for the first time placed within and instead of the magnets. It is understood that Mr. Gordon's machine has been "designed to take the place of large gas-vans as a central lighting station;" but, from what has been allowed to transpire respecting it, its bulk cannot be regarded as conferring on it any extra immunities from the risks of breakdown attending all dynamo machines. The sole apparent advantage of working large lamps from one machine, instead of feeding the same number of lights from 13 dynamos each supplying 100 lamps, is that all the lamps shall go out together instead of by groups.

ELECTRIC LIGHTING NOTES.

THE Edison Company have undertaken the lighting of H.M. troopships Serapis and Crocodile. Two sets of high-speed engines and two 250-light dynamos will be employed on each vessel; together with 400 lamps, a variety of fit candle and parts of accessories.

Messrs. A. and S. Gatti's restaurant, the Adelaide Gallery, is about to be lighted by Edison-Hopkinson (Z) machines. The light will be in duplicate throughout, consisting of two Field boilers, two Ingram and Royle high-speed engines, and four 140 Edison dynamos. The installation at the Hotel Métropole, which includes about 800 lamps, is now about to be increased by an additional 1000 lights, and when completed will be the largest of the kind in existence.

Messrs. Siemens Brothers have received an order from Messrs. Denny and Co., of Dumbarton, to apply the electric light to two vessels, Nos. 272 and 273, now building for the Compañia Transatlántica (Antonio Lopez and Co.) There are to be 90 lamps in each ship, fed by two generators (D S D?) each driven by a separate three horse-power Tangye engine. The power will be transmitted by Dynamos through friction pulleys, in the manner which has already proved very successful on the Aurania. Altogether there are five ships on the Clyde, receiving electric machinery from Messrs. Siemens Brothers, the aggregate number of these lamps being 1084. Besides these ships, Messrs. Siemens have in hand, including the Dumbarton vessel lead, the Manilla, and the Westerland, in course of construction at Laird's. Those of our readers who attend the forthcoming meeting of the British Association at Southport will have an opportunity of inspecting the kind of plant used by Messrs. Siemens Brothers on board ship, as that firm is taking advantage of the contract with the Association Committee to make a special display of this kind of machinery, which hitherto has not been seen at exhibitions. In the case of the frictional driving the dynamo is carried in trunnions with its pulley immediately over the flywheel of the engine, and the two shafts are connected by an adjustable torsion bar provided with brass steps at each end. Thus the wear resulting from the transmission is confined entirely to two extra bearings, and both engine and machine are relieved from strain.

THE LAST AND LARGEST DYNAMO MACHINE.

MR. EDISON is not to have the credit of designing and working the largest dynamo-electric machine in the world: this honour, such as it is at present, being claimed by Mr. J. E. H. Gordon, of London. The machine in question has been constructed and set to work at the East Greenwich works of the Telegraph Construction and Maintenance Company, where it is used to supply electromotive force to about 1000 Swan incandescent lamps distributed about the shops and offices. The machine appears to depart from the type of similar arrangements introduced of late years, wherein

THE EDISON ELECTRIC MACHINERY IN NEW YORK.

A detailed description of the machinery at the central station of the first district in New York City where the Edison system of electric lighting is to be applied, has been given in a paper by Mr. T. A. Edison and Mr. Charles Porter, read before the American Society of Mechanical Engineers. The district is not particularly described with respect to its location and area; but it will, when fully equipped, contain 12 dynamos, each capable of supplying 1400 improved 16-candle lamps, and driven by a horizontal steam-engine coupled direct to the armature. The engines have cylinders 21½ inches in diameter and 16-inch strokes, designed to run at 300 revolutions per minute. The steam is to be supplied from eight water-tube boilers of 3000 aggregate horse power. The boilers are fitted in the basement of the building, and the engines and dynamos are fixed on an iron superstructure over them, and entirely separate from the walls. The weight of each dynamo is 27,000 lbs., of which 9440 lbs. is the pure copper. The engine weighs 9446 lbs. The total weight of the united apparatus, including bed-plate, is 61,500 lbs. When working for a recent trial, while running among 1000 lamps, the engine indicated 159·4 horse power, and the corrected duty of the machinery showed 9·96 lamps per horse power. For 16-candle lamps this is consequently 149·70 candles per horse power, which is a very good result, taken, it must be remembered, under test conditions. The degree of perfection of the machinery may be inferred from the statement that the losses of efficiency due to undiscovered resistances averaged only 0·4 per cent. It is perhaps needless to say that the expenses of the establishment are not treated of in this paper.

Engineering, Dec. 1, 1882.

THE FERRANTI-THOMSON ELECTRIC MACHINE.

A RECENT correspondence in the *Times* has doubtless rendered the name of the Ferranti machine familiar to many of our readers, but it was not until the beginning of the present week that its form and construction were made public, a delay having occurred in perfecting improvements made in the machine, as well as the securing of the patent rights for the invention.

The Ferranti-Thomson machine—which is the joint invention, or, to speak more correctly, a combination of the inventions of Mr. S. Zimi de Ferranti and of Sir William Thomson—is an alternating current machine of an exceedingly interesting and original type, the special characteristic feature being the armature, which contains neither wire nor iron, and is of such small dimensions and weight that it can be rotated at a very high velocity between the magnetic poles, which are only separated by a distance of three-quarters of an inch, and therefore within a magnetic field the intensity of which can hardly be approached by any machine with which we are acquainted.

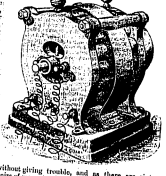
It is impossible to see, for the first time, this remarkable little machine running, without being struck with its exceptionally small size as compared to the work it is capable of doing, for on the occasion of its first exhibition to the public it was illuminating on one circuit no less than three hundred and twenty "20-candle" Swan lamps, equal to a luminous intensity which we should estimate at from fifteen to seventeen candles, although its total weight is but 60 cwt., and the whole machine measures only 24 in. × 20 in. × 18 in.

In general external appearance the Ferranti machine, as will be seen from the illustration on the present page, has some resemblance to the well-known Siemens alternating, and Wilde machines, but the resemblance is only superficial, for not only are both the armatures and construction and arrangement of the field magnets perfectly distinct from either and which is under one of the arches of the Cannonof those machines, but the principle of action instead Railway Station, the apparatus is driven by altogether different. The form and construction of Messrs. Fowler's semi-portable 16-horse of the Ferranti armature may be understood by imagining an eight-toothed pinion, 18 in. in dia-power, and this drives, through the intervention of meter, and 4 in. thick, around which are loosely wound two thick turns of copper ribbon 4 in. wide, having an insulating band of the same width wound to the armature of about 7000 ft. per minute, a with it, so as to insulate contiguous convolutions velocity which, by reason of the extreme lightness from one another; if now by any mechanical con- of the moving parts, is in no way inconvenient, and trivance such, for example, as causing the pinion so coiled to gear into another similar wheel the copper ribbon be forced into the spaces between the teeth, an undulating outline, which will be parallel to that of the circumferential surface of the pinion on which it is wound, will be given to it, and if the pinion be then removed, the copper strip will be left as a hollow pinion-shaped gear, through the axis would to all intents and purposes be a Ferranti armature.

The armature is composed of a continuous strip of copper ribbon 120 ft. long, half an inch wide, and one twelfth of an inch thick, coiled upon itself in twelve layers with an insulating tape between the convolutions, and having the undulating or pinion-shaped outline which we have already described. There is no iron core to this armature, the interior space being quite open, thus permitting of free circulation of air in and around the copper coil while the machine is running. The whole of this portion of the apparatus weighs but 18 lb., and this is perhaps the most interesting feature of the machine, for there is certainly no other electric generator at present in the field, that with an armature weighing but 18 lb. can render incandescent 320 Swan lamps, that is to say, nine-tenths of an ounce weight of moving armature per lamp of sixteen candles.

The small size of the armature, and especially its extraordinary thinness (only half an inch), enables it to be run within a correspondingly narrow magnetic field, and therefore one of exceptionally high intensity. The field magnets are arranged in two crowns around a pair of discs of cast iron, which form the outer framework of the machine, their free ends, which constitute the poles of one set of magnets, being directed towards the free ends of the opposite set, and towards the armature which rotates between them. Each crown is built up of sixteen electro-magnets, which are, like the armature coils of the Wallace-Farmer machine,* sector-shaped in cross section, and the exciting coils with which they are wound are also of similar shape; in fact, if the sketch given in our article on the Wallace-Farmer armature were altered so as to show a crown of sixteen coils instead of twenty-three, it would convey a very fair idea of the arrangement of field magnets in the Ferranti machine. As, however, the current generated by this machine is alternating in character, the field magnets have to be excited by a separate machine, and for this purpose a small Siemens D, machine is employed, the current from which represents about two horse power of electrical energy. The magnets, of which there are thirty-two, are wound 6 in. long, and are each wound with one hundred and forty turns of insulated copper wire of about No. 10 B.W.G., and are all connected together in series in such a manner as to alternate a polarity around the crown, so that any fixed point in the armature passes alternately a north pole, and a south pole

* See ENGINEERING, vol. xxvii., page 309.



at its rotation around the axis. The weight of copper on the field magnets is about 81 lb., and the total resistance of the exciting coils, of which 24 ohms belong to the armature coils, is 8 ohms.

The installation to which we have referred, engaging at the flywheel about 26 horse-horse-power, and the latter, through the intervention of Swan lamps per horse power when 320 are in circuit is about 12.

We need hardly point out to our readers that the above figures if substantiated, show for the Ferranti-Thomson machine a remarkably high efficiency, and this is, in our opinion, due to the fulfilment, to an exceptional degree, of three elements which should, among certain other things, be contained in a theoretically perfect machine.

1. Small weight of moving conductor.
2. High velocity of ditto.
3. Intense magnetic field.

The first is obtained by the peculiar shell-like character of the armature with no iron cores to add to the weight, or to absorb energy either in the production of local currents, and therefore of heat, and these conditions control the second element, enabling the machine to be run with advantage at a high velocity. The third element of efficiency is rendered possible to an exceptional degree by the form and dimensions of the armature, for, as that part of the armature is but ½ in. thick, the poles of the magnets can be approached to within a small fraction of an inch of that distance, and the convolutions of the armature are thus under the best possible condition to be influenced by electro-magnetic induction, and this fact is alone sufficient to account for a large proportion of the efficiency of the Ferranti machine.

We may state that the owners of the machine and system are a private company; Messrs. Ferranti, Thomson, and Ince, whose object is to manufacture and sell the machines and apparatus covered by the patents, and not to form subsidiary companies or grant licenses for exhibiting the objects for which they themselves are established. We understand, however, that the Hammond Electric Light and Power Supply Company possesses the exclusive right to use the Ferranti machine so far as this country is concerned, and we have little doubt that it will before long become largely employed for incandescence electric lighting.

Certain commercial reasons connected with the patents under it undesirable to publish at this date more detailed drawings or descriptions of this very interesting machine, but we shall in a short time be free to do so, together with accurate data of its performance, so that our readers will be able to form their own opinion of the merits of an electric generator which is at the present time the greatest novelty in the world of electric science.

There is no commutator to the machine, the armature being connected to the outside circuit in a manner precisely similar to that adopted in some of the early Siemens machines—that is to say, one end of the armature conductor is permanently connected to one metallic collar fixed to and forming part of the spindle upon which it rotates, and the other end is attached to another similar collar fixed to the spindle, but insulated from it. Upon the circumference of each of these collars is pressed a piece of short lever, so as to maintain a good rubbing contact, and these two levers are connected, the one to one terminal screwed into the framework of the apparatus.

On the occasion of the first exhibition of the machine the 320 lamps were arranged in 102 groups, that is to say, 100 groups of three lamps, each in series, and one group having two lamps in series, and the constancy of illumination at a constant speed of the engine was all that could be desired. With 300 lights in circuit the electrical energy being thrown into the circuit was about 224 horse power, and if, as we are told was the case, the engine was at that time giving off 26 horse power, the machine would show an efficiency of about 86½ per cent., after allowing for about two horse power of electrical energy representing the magnetising current from the small machine; we shall, however, before long be able to give accurately determined data.

The following are some of the figures connected with this very interesting machine and installation:

Resistance of armature	...	.0265 ohms.
Total resistance of circuit	...	.7200 "
E. M. F. in main circuit	...	122 volts.
Current	...	156 amperes.
Resistance of lamps, each	...	31.5 ohms.
Current absorbed by each lamp		1.5 amperes.
E. M. F. taken	"	47 volts.

The weight of armature and collars is about 1260 lb., or 13 volt-amperes per pound weight of apparatus; the number of Swan lamps per horse power when 300 are in circuit, is about 11½; and the number of

The efficiency of the machine as an experimental machine, without any attempt at special construction, is about 90 per cent., and the machine will work without giving trouble, and as there are sixteen pairs of magnets of alternating polarity, it follows that there are no less than 500 reversals of the current for every second, or 30,000 per minute.

capital. In our next article we shall deal with bills deposited by companies on the south side of the Thames.

THE CHERTEMPS-DANDEU DYNAMO MACHINE.

In my system which includes private or domestic electric lighting the necessity of providing some means of regulating the generative power of the machines in accordance with the requirements of the mews has to be considered. In a circuit of arc lamps the extinction of one or two is usually followed by an increased brilliancy in the remainder, while if a large proportion is cut out there is great danger of burning the insulation of the generator. With incandescence lamps arranged in parallel are

Fig. 1.

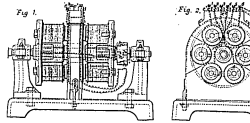


Fig. 2.

the same effect is produced, except that it is usually the lamps that suffer from the increased current. The leading manufacturers of electric light apparatus have each their own method of dealing with this difficulty. Mr. Brush long ago devised a plan of regulating the current by means of a variable carbon resistance arranged as a shunt across the magnet coils. This was subject to a pressure obtained by passing the current that was to be regulated round an electro-magnet, and allowing a portion of the exciting current, dependant on the current in the main circuit, to run to waste. We have heard that this system gave good results in America, but we are not aware that it has been employed to any extent in this country, indeed few of the installations carried out by the Brush Company have been of a nature to require it. Mr. Edison varies the productive power of his generator by modifying the resistance and consequently the current in the circuit of the field magnets. This is effected by an attendant, who, using a lamp and a photometer as a measure of the difference of electric potential between the two main leads, switches resistance boblbins in and out of the magnetizing circuit as required. Mr. Edison has also many patents dealing with the same subject, but in none, so far as our memory serves us, is the regulation effected without mechanical motion in some form. Dr. Siemens' method of accomplishing this object consists in making the magnetizing coils a shunt to the main leads and in so proportioning the diameter of the wire and the number of convolutions that the electromotive force of the current is usually constant. In the small machines adopted to large 20 to 25 lights this seems to have been very successfully carried out, as the number of lamps can be decreased to one or two without danger, but in the larger machines, feeding a hundred lamps and upwards, the safe variation is confined to 20 or 25 per cent. We have heard a rumour of a machine of much larger size by the same firm, with a modified form of shunt winding that is said to give very reliable results, but we believe that it has not yet been tested to actual every-day practice. The Swan Company have hitherto used the Siemens alternate current machine in their larger installations of incandescence lights, as have also Messrs. Siemens Brothers themselves. This is a separately excited machine, and consequently if its internal resistance be small as compared with the combined resistance of all the lamps and leads, the difference of potential at its terminals is pretty constant, and it will permit of a considerable proportion of the lamps being extinguished without unduly increasing the current supplied to the others.

So far none of these schemes have met with more than a partial success, and that in this country only in conjunction with incandescence lighting. A new dynamo, patented by MM. Chertemps and Dandeu, is now for the first publicly shown, for which it is claimed that it entirely solves the difficulty, and that whether it be employed to feed arc lamps arranged in series or incandescence lamps in parallel the number of lamps may be varied from the full number, corresponding to the maximum power of the machine, down to one, without any appreciable change in the illuminative power of each lamp. This is effected without any manipulation or mechanical operation whatever, the intensity or the electromotive force of the current automatically changing at each alteration in the circuit without any attention, and without any variation in the speed of rotation.

Referring to the illustrations on the present page, which show the machine inside and out elevation and also in perspective, it will be seen that it belongs to that class in which the armature bobbins are stationary while the field magnets revolve. The armature bobbins are fixed in a wooden frame erected on the saddle of the base-plate. Lengthwise of the machine, and passing through the centre of the armature frame, is a shaft having mounted upon it two metal discs, to each of which a set of field magnets, equal in number to the armature bobbins, is affixed. These magnets, as usual in alternate current machines, are alternately north-pointed and south-pointed, and each pole of one set is opposite to a contrary pole of the other set. The terminal wires of each of the armature bobbins are carried up to a grouping table and attached to separate binding screws. The pursuits of them being joined up in series or parallel, or divided into independent circuits as may be desired, even without stopping the machine. One of the armature bobbins is appropriated to the work of exciting the field magnets, its current being led first to a commutator, by which it is transformed into a continuous current, and then round all the magnet coils, the whole forming a closed circuit. The commutator is so constructed that one section does not leave the brush before the next section is in contact with it. It may be described as composed of two hollow cylinders, each with a closed end, their peripheries being cut away so as to permit of these interlocking to the full length of the cylinders. There are as many interlocking parts or teeth as there are magnets in each field, each part is cut into steps, as shown, so that at the junction the collecting brush can bear upon both of them, and thus short-circuit the exciting bobbin at the moment when the field magnets are passing the spaces between the armature bobbins. It will thus be seen that there are usually two circuits on the machine, one consisting of all the armature bobbins (except one) and the external or lamp circuit, and the other of the single remaining armature bobbin and the field magnet coils. Two of these machines, a small and a medium-sized one, have been tested by Mr. Robert Sabine. As regards the small one, he reports that it was employed to feed eight Jablochkoff candles which were added to the circuit two by two, and that whether it be employed to feed arc lamps arranged in series or incandescence lamps in parallel the number of lamps may be varied from the full number, corresponding to the maximum power of the machine, down to one, without any appreciable change in the illuminative power of each lamp. This is effected without any manipulation or mechanical operation whatever, the intensity or the electromotive force of the current automatically changing at each alteration in the circuit without any attention, and without any variation in the speed of rotation.

Referring to the illustrations on the present page, which show the machine inside and out elevation and also in perspective, it will be seen that it belongs to that class in which the armature bobbins are stationary while the field magnets revolve. The armature bobbins are fixed in a wooden frame erected on the saddle of the base-plate. Lengthwise of the machine, and passing through the centre of the armature frame, is a shaft having mounted upon it two metal discs, to each of which a set of field magnets, equal in number to the armature bobbins, is affixed. These magnets, as usual in alternate current machines, are alternately north-pointed and south-pointed, and each pole of one set is opposite to a contrary pole of the other set. The terminal wires of each of the armature bobbins are carried up to a grouping table and attached to separate binding screws. The pursuits of them being joined up in series or parallel, or divided into independent circuits as may be desired, even without stopping the machine. One of the armature bobbins is appropriated to the work of exciting the field magnets, its current being led first to a commutator, by which it is transformed into a continuous current, and then round all the magnet coils, the whole forming a closed circuit. The

* The curious result in these measurements were apparently of inferior quality.

When the field magnets are in motion, each magnet, as it approaches one of the bobbins of the armature, exercises an inductive action on the core of the latter, inducing its corresponding extremity with an opposite polarity to its own, and generating a current within its convolutions. The direction of this current is such that it reduces the polarity of the core, and thus the magnetic intensity of the interior soft iron in the armature, of the two opposing actions of the armature coil and of the field magnet. At the same time the polarity of the core has an influence upon the polarity of the field magnets, and in this way affects the exciting current in a marked degree. To make this plain let us trace the action of one of the field magnets, indeed with, say, north polarity at its free end, upon one of the armature coils. When the external circuit is open, that is when it has an infinite resistance. As the magnet approaches the end of the bobbin core it induces a south pole in it, and the two are mutually attracted. As it leaves the core the attraction is still continued, but in a contrary direction as regards the driving power. Thus when the field magnet passes the core there is no action upon it except such as would be produced by the presentation and withdrawal of a piece of soft iron from its pole. But now suppose the external circuit be completed by the introduction of ten arc lamps in series. As the magnet approaches the core not only does the latter become magnetised, but a current is generated in its surrounding coils that opposes the increase of its polarity, consequently it no longer behaves like a piece of soft iron, but rather as a weak permanent magnet that must have its natural polarity reversed by the induction of the field magnet before it will fulfil its office. But this reversal distorts the lines of force around which the current coils are grouped, and in so doing sets up an opposing electromotive force within the conductors that reduces the exciting current, and consequently the intensity of the magnetic field. This reduction is a most exciting bobbin, and the magnetising current is further reduced, resulting in a decrease of current or of electromotive force in the external circuit. If the resistance of the circuit be again decreased by short-circuiting one of the lamps there will be a momentary increase of current, but this will further oppose the magnetisation of the cores, and will again effect the diminution of the intensity of the magnetic field. The process of reduction will be continued until the bobbins short-circuited, when, if it be properly proportioned, the influences of the armature and the magnets will be almost equal, and the exciting current will nearly disappear.

NOTES.

THE THOMSON EFFECT.

SIR WILLIAM THOMSON first discovered that when an electrical current passes through a piece of metal, the ends of which are kept at different temperatures, it exerts heat with it in a direction depending on the character of the metal, and the sending on the character of the metal, and the sending on the character of the current. This effect by M. Le Roux, the discoverer's name, was verified in 1871, and also gave a table of thermoelectric position with several different metals. Quite recently Mr. John Trowbridge and Mr. Charles B. Penrose, of the Physical Laboratory, Harvard, made further experiments on

ELECTRIC LIGHTING NOTES.

Last Friday the case of Phillips *v.* the Great Western Electric Light and Power Company was heard before Mr. Justice Chitty. It was an application by a holder of ten shares for the rectification of the register by striking his name from the list of shareholders, on the plea that the prospectus issued by the directors of the company was not answered and misleading, in that it stated that they had acquired the exclusive right to the use of the Brush system of lighting in a district that included a considerable part of the West of England and South Wales. It was affirmed in the affidavit supplied by his counsel, Mr. Waller, Q.C., and Mr. F. T. Prentor, that on July 29, 1881, Mr. St. George Lane-Fox assigned to the British Electric Light Company the exclusive right of using and granting licenses for its inventions in Great Britain and Ireland, and that on July 28, 1881, he executed a similar assignment to the Anglo-American Brush Corporation, subject, nevertheless, to the previous assignment, and that it was, therefore, incorrect to assert that the Brush Company were the sole possessors of the patent. For the defendants, Mr. Bonner, Q.C., and Mr. Pilgrim Beale, contended that the misstatement, if there were one, was immaterial, as the value of the Lane-Fox assignment is insignificant, and the plaintiff has suffered no substantial injury. In delivering judgment, Mr. Justice Chitty said that although there was no bad faith, but only some carelessness imputed to the framers of the prospectus, yet it was plain to an unprejudiced mind that there had been a misstatement that was material, and calculated to mislead the applicant. His lordship did not think that expressing any opinion himself one way or the other as to the value of the Lane-Fox invention, though he understood that many persons who had handed in prospectus, which began beginning to emit had recommended as one of its leading features this particular invention, to afterwards say for the purpose of upholding their prospectus that the invention was of little or no value, and therefore was not a chief attraction of the scheme. He ordered the plaintiff's name to be removed from the register, and the money that he had paid to be returned to him. We suppose that this decision will be appealed against, and therefore it appears idle to speculate upon the ultimate effect of the action upon the Brush companies, until the higher court has given its decision. It is, however, probable that the patent company, which has lately received and distributed among its many, been a large amount of money, has made a call of 20 upon each share. It is a struggle are the sinews of war more necessary than in a legal one.

Since the commencement of the month the Manchester Exchange has been lighted by ten new Brockie arc lights, of 3000 candle power each, and 400 incandescent lamps of fifteen candle power each. The installation has been effected by the British Electric Light Company, who have also just fitted the United Steamship Company's vessel, Kjobenhavn with a number of incandescence lamps and one arc light. The former are tastefully arranged in the different parts of the ship upon brass gilt fittings, representing mermaids. The same firm are lighting the British India Steam Navigation Company's ship Peera with 320 incandescence lamps and one arc lamp. They have likewise in hand, and approaching completion, installations at the oil mills of Messrs. Walker and Son, King's Lynn, and at the stores of the Civil Service Supply Association in Bedford-street, W.C.

The electric arc light is beginning to replace the limelight in the production of theatrical effects. On Saturday evening last the beam from a powerful arc regulator, supplied by the Duplex Electric Light Company, Storage Company, was introduced into the performance at Mr. Charles Reade and Mr. Pettit's drama "Leon and Nancy" at the Adelphi Theatre. In this thrilling melodrama of the old Adelphi school there is a villain, a scene and an explosion which entombs several of the characters. They are afterwards dug out by a rescuing party, and all the incidents of relief in such a case are represented. When the obstructing coal is cut through a flood of artificial daylight from the electric lamp and a reflector is poured through the gap into the crowd gallery. The luminous effect is far more powerful and like daylight than could be given by a lime-light. We may also add that the same company are, under the direction of their engineer, Mr. F. Crocker, and Mr. Harris, lessee of the theatre, at present engaged in fitting up the stage of Drury Lane with arc and incandescence lights for the forthcoming pantomime of "Sindbad," in which some novel effects will be presented.

Messrs. Farnley and Son, of Harmer-street, W., have, we believe, designed and manufactured the special fittings ordered for the Swan lamps that are being supplied to H.M.S. Himalaya. There are of a less fanciful type than those originally made by the same firm for the Soudan, the main requisite in a troop-ship being safeguards against tampering.

Further details are to hand regarding the contract recently entered into between the Gas and Lighting Committee of the Town Council of Aberdeen and the Scottish Brush Electric Light and Power Company for the experimental lighting. It has been decided that the trial shall be carried out in several of the most frequented thoroughfares in the centre of the city, including Castle-street, part of Union-street, and Market-street. Two lights will likewise be placed in prominent positions on the bridges over the railway in Guild-street and Union-street. It is anticipated that the streets selected will afford an excellent opportunity for testing the system. The distance at which the lamps will be placed apart from each other will vary according to circumstances and the position of cross streets; but the average distance will be from 70 to 80 yards. They will in each case be set on posts at a height of 20 ft. from the ground, and in clear glass globes. The house in which the engine and dynamos are placed is situated in College-street. Two Brush lamps of new design, for interiors, are also to be used in the illumination of the large public hall in the Municipal Buildings. One will be hung about 25 ft. above the floor of the hall, and the other will be suspended in the wall of the grand staircase in such a position that it will afford an abundance of illumination to the whole of the entrance corridors and portico.

At the last meeting of the Glasgow Corporation Gas Committee the town clerk reported that, on the conference of representatives of corporations, relative to the Electric lighting provisional orders to be applied for in the ensuing session of Parliament, had taken place in London on the 15th ultimo, and that, along with Mr. J. L. R. Jamieson, convener of the Gas Committee, and Mr. Fowlis, the general manager, he had assisted at the conference, as representing the Glasgow Corporation. It was largely attended by representatives of numerous towns, and all those who were present resolved to act in unison, and upon the same lines, so far as the interests of each particular body represented admitted of that being done. A copy of the resolutions passed at that conference having been read, it was explained that, under the remit made to them, the town clerks of Glasgow and Manchester had adjusted the terms of the provisional order, which was to be submitted to all the municipal corporations for their consent approval and adoption. The orders, as so adjusted, is to be considered at an aggregate meeting, about the end of the present month, and, when finally adjusted, it will be submitted to the Board of Trade at once in reference with the Provisional orders, when it is proposed to have the views of all the corporations represented by counsel retained. A copy of the draft provisional order as now prepared was submitted and explained in detail. It was further reported that at the last conference the general feeling seemed to be that if, after the case of the corporations had been fully placed before the Board of Trade, the Board were not disposed to grant orders to some of the corporations upon the lines of the draft order as finally adjusted, then the united corporations should agree to take orders, and represent their conjoint views to Government and to Parliament. In any case, it should be the endeavour of all the corporations to secure that no orders or licenses should be granted by

the Board of Trade to private persons or companies which did not contain stringent provisions obliging them to fulfil the obligations which they might undertake, and to find reasonable security that they should do so, before they were allowed to open streets or to acquire any vested or saleable interest under any such orders or license. The Gas Committee unanimously approved of what had been done at the conference in London, and also approved generally of the principles on which the draft order submitted had been based; and they gave further instructions to the town clerk as to his future actings. The subject came up for consideration at a meeting of the Town Council held on Thursday, the 7th inst., the principal speaker being Mr. W. Henry Wilson, a member of an engineering firm in whose works electric lighting is very extensively used; but the discussion was not continued as the Lord Provost urged that the matters referred to were of so delicate a nature that they had better be left in the hands of the Committee. He said, however, that if the provisional order as finally adjusted did not satisfy the Council they could drop it & not put it in operation.

this lamp is extremely simple in its arrangement and working. As regards the light produced, it should be pointed out, that owing to the construction of the lower part, and to the presence of the counterweight, a marked reduction of light is noticed beneath the lamp, though this does not amount to an actual shadow on account of the large size of the upper carbon. This disadvantage will probably be removed by modifying the details of the lower part, in which direction has been chiefly directed to the production of a direct light. The counterweight may be easily applied to the top of the lamp, and the interception of the light will be thus avoided.

GEOGHEGANS LOCOMOTIVE.

In our last number but one we illustrated and described (see page 529 ante) a small shunting engine, employed at the Cold-harbour brewery of Messrs. Guinness, Son, and Co., at Dublin, this little locomotive having been constructed from the designs of Mr. S. Geoghegan, the engineer of the establishment. In publishing an account of the working engine, we promised to illustrate some further details, and this we now do, our additional engravings appearing on page 573.

In the illustrations now published, figs. 30 to 40 show the details of the steam brake, this consisting of a cylinder fitted with two pistons between which the steam is admitted. The pistons when forced outwards by the steam exhaust cross-heads which extend right across the engine, as shown in the general plan, fig. 1, page 522 ante, each cross-head carrying at each end a vertical rod-iron brake block, which it can thus force directly against the corresponding wheel. Each cross-head is coupled by a pair of links to a cross-bar, which likewise carries brake blocks at its extremities. These four cross-beams when forced forwards by the pressure of the compressed steam, forces the two blocks at the extremities against the front pair of wheels, and draws another pair of brake blocks (by means of the links and cross-bar, as just mentioned) against the hind pair of wheels. The steam brake may be used by the engine alone, brake blocks being fitted to the hind pair of wheels, and draws blocks into contact with the front pair of wheels. Strong springs tend to force the two cross-beams together, and thus keep the pistons back in their central position, when the pressure in the brake cylinder is relieved.

Figs. 41 to 44 show the details of the connections to the brake frames of the long spring plates which are screwed to the top and bottom of the axle-boxes, as described by us in our former notice. The arrangement will be readily understood when comparing Figs. 41 to 44 with the general views on pages 522 and 573 ante.

The details of the firegrate, hollow bridge, and fire-door front, are shown by Figs. 45, 46, and 47, page 574. A reference to the longitudinal section of the engine, page 522 ante, will show that the grate is of the ordinary multitubular type, it being cylindrical with a cylindrical combustion chamber, 2 ft. 10 in. in diameter outside, and 2 ft. 10½ in. long between tube-plates, extended to the same length by the design of Mr. S. Geoghegan, the author of the establishment. In publishing an account of the engine, we promised to illustrate some further details, and this we now do, our additional engravings appearing on page 573.

In the illustrations now published, figs. 30 to 40 show the details of the steam brake, this consisting of a cylinder fitted with two pistons between which the steam is admitted. The pistons when forced outwards by the steam exhaust cross-heads which extend right across the engine, as shown in the general plan, fig. 1, page 522 ante, each cross-head carrying at each end a vertical rod-iron brake block, which it can thus force directly against the corresponding wheel. Each cross-head is coupled by a pair of links to a cross-bar, which likewise carries brake blocks at its extremities. These four cross-beams when forced forwards by the pressure of the compressed steam, forces the two blocks at the extremities against the front pair of wheels, and draws another pair of brake blocks (by means of the links and cross-bar, as just mentioned) against the hind pair of wheels. The steam brake may be used by the engine alone, brake blocks being fitted to the hind pair of wheels, and draws blocks into contact with the front pair of wheels. Strong springs tend to force the two cross-beams together, and thus keep the pistons back in their central position, when the pressure in the brake cylinder is relieved.

Figs. 41 to 44 show the details of the connections to the brake frames of the long spring plates which are screwed to the top and bottom of the axle-boxes, as described by us in our former notice. The arrangement will be readily understood when comparing Figs. 41 to 44 with the general views on pages 522 and 573 ante.

The details of the firegrate, hollow bridge, and fire-door front, are shown by Figs. 45, 46, and 47, page 574. A reference to the longitudinal section of the engine, page 522 ante, will show that the grate is of the ordinary multitubular type, it being cylindrical with a cylindrical combustion chamber, 2 ft. 10 in. in diameter outside, and 2 ft. 10½ in. long between tube-plates, extended to the same length by the design of Mr. S. Geoghegan, the author of the establishment. The holler is 2 ft. 5¼ in. long between end plates, and 6 ft. 4½ in. in diameter inside, and is fitted with 71 tubes, 2 in. and 2 ft. 10½ in. long from the tube-plate to the inside of the fire-box front. The arrangement, as shown by Figs. 45 and 46 on page 574, it will be seen that the firegrate is composed of six water-tubes, each 2 in. and 2 ft. 10½ in. long from the tube-plate to the inside of the fire-box front. These tubes are connected at their outer ends to a hollow bridge, which is constructed with a water-space all round it, so that the water in the interior of the hollow cast-iron bridge can communicate with the water-spaces in the fire-box front. The bridge is also connected to the holler, whereby it will be seen that the perforated plate shown in Fig. 45, this plate, which comes next the fire, being made so as to be easily removable.

The last details we illustrate on page 574, are those shown by Figs. 48 to 52, these views representing the boiler mounting carrying the safety valves, whistle, steam-cocks, pressure gauge, &c. As will be seen from the engravings, the mounting is constructed so as to serve a variety of purposes, from the safety valves to the tests to the boiler, and it constitutes among other attachments, a convenient fitting. Altogether this boiler mounting is marked by much originality of design, and possesses many features of special interest.

THE WESTON SYSTEM OF ELECTRIC LIGHTING.

(Continued from page 560.)

In our next illustrations, 10 and 17, we show a form of feeding mechanism, which Mr. Weston has devised for the feeding of the carbons in his system of brake-wheel lighting. In this arrangement the carbon is attached by means of which the upper carbon receives a sliding lever M, which is provided with a suspension rod, and at the other end is fitted to an oval-

ing lever K. Two sidelevels, F and R, of peculiar form, are used for the purpose of regulating the position of the levers. One of these levers is included in the main circuit, and the other in a derived circuit between the upper and lower carbons at the ends of the lever by flexible metallic strips *f* and *h*. The wheel W is controlled by a brake A, which is pivotted to the lever M, but outside of the periphery of the wheel, and has a short arm at the right to which is attached a rod or wire at C. It also has a projecting arm at the left, extending over and resting upon the frame of the lamp at C. The working position of the wire rods is shown at the left, in Fig. 17, these rods shell and part of the coil are cut away to allow the arrangement. It will be seen that the solenoid has the ordinary over, and in addition, an iron shell surrounding the coil, and having a gap in one place with the core. Mr. Weston has found, that with a solenoid constructed in this way, an extremely long range of motion can be obtained with very uniform power; and that the solenoid is about as powerful as an ordinary fil-bunched electro-magnet, having double the amount of wire upon it. The great disadvantage of ordinary solenoids is their comparative feebleness in proportion to their size.

Supposing the lamps to be at rest, with the carbons in position, and burning, applying the current the solenoid of the oscillating lever, and draw down its end where the feeding levers are connected. The lever then tilts over, and in addition, as iron shell surrounding the coil, the lever 2 and the wheel up locally, so as to separate the carbons and form the arc. As the arc increases in length, the current through the solenoid is reduced, and the attraction of the iron shell upon the lever diminishes. It rests upon the wheel with sufficient force to retain the brake and allow the wheel to rotate. When the carbons burn away to the length of the arc will immediately set the brake, and the slightest increase release it. The wheel will rotate, and the lamps is so arranged with the carbons that the wheel, that the weight of the carbon not its carrier tends to rotate the brake when its detaching attached lever, and the current form, and is nearly is very positive; but the moment the arc is formed, the attraction of the solenoid becomes larger, and the lever over the brake, the device works with very great accuracy. The feeding is very simple and extraordinarily accurate, it is evident that it is impossible to detect the movement of any one lamp.

In Fig. 18 we shown the automatic cut-out, ordinarily used with these lamps. It is a modification of the well-known Weston cut-out, and consists of an electro-magnet in the same circuit with the lamps, which when the armatures is released by the magnet. This cut-out is attached to every convenient form, and is usually placed near the lamps, as shown at the left in Fig. 17, being included in the casing with the electrical connections. The diagram indicates clearly the method of connecting a few sets of bunched or famous silver wire, which are included in the shunt circuit, the current passing from the main conductors down in the same direction as in the lamps coil, and the object of the supplementary coil is to cause the armature to be held more quickly to open the circuit when the lamp is lighted. The resistance of the shunt coil is very great, when all the lamps are lighted, but when the carbons is reduced, it is much less, and the current closed, and the lamp circuit opened. The resistance of the cut-out is adjustable, and it is sometimes found necessary to increase or decrease the resistance, but from the fact that the magnet is also included in the circuit, the armature is held by its armature. Whenever the lamp circuit is closed, however, the current at first divides between the two circuits, as in the magnet, and built to operate. The resistance very quickly reduced the shunt is broken, and the current passes through the lamp. This cut-out is very simple, and is very efficient under ordinary circumstances, but where a very large number of lamps are used in the same circuit, a number of cut-out shunts is found necessary. For the sake of additional precaution to guard against any dangerous disarrangement of the arc.

J and N are insulated contact pieces, leading from the binding-posts of the lamp, and terminating in contact pieces, which form a spring switch, being shown in the illustration. The switch is opened by the pressure of a spring, but is usually held open by a catch, which is pivotted to the upper part of the switch, and arranged between the jaws of the switch, as shown in the plan view, in the lower upper section, but at a sufficient distance from the upper end to allow the hanging of the fusible plug which is attached to it. This arrangement is so simple as to require no description, and it will be seen that the switch is closed by the fusible plug is melted, and the switch is closed by the spring, and the lamp cut out. This switch arrangement is so extraordinarily sensitive, that the slightest variation, caused the united springs on the lever would close the battery circuit, by making contact with a stop-screw in the lower part of the lever, and ring a bell at the top to call the attention of the attendant to the means of this indicator, the attendant at the central station can see, upon starting the machines, that the proper current is sent to the lamps, and he discovers at once whether any accident occurs to the circuit, or when lamps are put out of circuit or switched out, can immediately adjust the machine to compensate for the change.

The Weston incandescent lamp has been long in use, and is already so well known that we need not give any detailed description of it.

The different incandescent lamps of the public safety devices which we have invented. With the multiple system, it is the custom that the diameters of the current are small. The internal dimensions depend upon their relative resistance. By the arrangement of one of the branches of current would be diverted to it from the main current, and this might be sufficient to dangerously heat, or even fuse the branch wire. A safety device, of the form illustrated in Fig. 29, is placed in each branch, to guard against this danger. It consists of a strip of easily fusible alloy introduced into the branch wire arranged in convenient form for removal. The alloy is composed of tin, lead, cadmium, and bismuth, and fuses at a temperature of 75 deg. The strip is made of sufficient size to support the normal current without heating it to its fusing point; but when the branch conveys a greater flow of current, the heat of the branch conveys a greater flow of current, the heat of the branch conveys a greater flow of current, the heat of

Electrical Review, July 19, 1883.

Experiments on Dynamo-Electric Machines.

THE ELECTRICAL DETERMINATION OF THE EFFECTIVE VALUES OF THE PASSIVE MECHANICAL POWER, THE INTERNAL RESISTANCE, AND THE MAGNETIC FIELD AT GIVEN DEGREES OF INTENSITY.*

The object of these determinations is to ascertain accurately the loss of power and the electrical results in various mechanical apparatus; I have made use of various methods of determination of which I shall only quote the following summary, which is general, correct and simple; the practical arrangement of two galvanometers, one of very low, the other of very high resistance, called electromotive force and intensity galvanometers, which I advocated in 1870, is adopted.

I would call attention to the fact that after having shown that the usual approximate laws and formulæ are, in several respects, insufficient to represent the working of the machines, and that it is necessary to take into account the important reactions which are by no means neglectable, I have proved that the most accurate and the most practical method is to sum up all the effects of various kinds, and to include them in one or the other of the following two effective quantities:

The effective magnetic field, the effective internal resistance; these two quantities having to be determined by experiment.

We shall represent the effective field by φ, the electromotive force which it produces with a given degree, for a given length or thickness of the induced circuit.

We shall call n, the degree $n\varphi^2$, the difference of potential at the terminals of the machine as generator and as receiver; t, t' the power in kilogrammeters that indicated at the brake as a receiver, and that absorbed by the passive mechanical resistance of the machine.

These are the data, all observed directly, except the last, r, which is assumed. (I shall show further on how it is determined.) The three unknown quantities to be determined are: First and second, the electromotive forces as generator and as receiver, e, e', which will be furnished by the forces of the fields, which may be equal, a little different, or very different, as I have pointed out upon several occasions (notably *à propos* of the experiments of ploughing at Semalay, and of the electrical transmission of power at Miesbach-Munich), according to the constitution of the static field; third, the effective or *dynamic* resistance, r, which must not be confounded with the *static* resistance, a, that is to say, with the ring at rest; r exceeds a relatively more as the speed, fineness and length of the circuit per pair of brushes are increased; r, therefore, takes into account, under the form, $t^2 \Delta \alpha$, the deficit of work of machines with a collector, a deficit of an electrical nature, of which I have had first the honour of giving to the Académie the indication and measurement.

From the three equations—

$$e_n = g\frac{(t+t')+\sqrt{(t+t')^2-4\,t\,t'\,r^2}}{2}, E_n = g(t+t')_m, E_m r^2 + I^2 = t\,t'$$

we find

$$r = \frac{t+t'}{I} - g\frac{t+t'}{I\,I_1}$$

$$E_m = g\frac{t+t'}{I} - I(r+a)$$

(gross electromotive force)

$$g = \frac{t}{I}$$

and $g = \frac{t'}{I}$ (nett force)

$$\therefore E = \frac{t+t'}{I} - I(a+r)$$

We have just assumed r to be known; here is a purely electrical method of determining it.

Separate the circuit of the electro-magnets from the induced circuit; excite successively the conductor with any two currents, provided that the forces of their respective magnetic fields be not equal; make to pass successively, by induction, a current, so that the speed becomes n, under the only passive resistant couples of the galvanometers, this current I and I' and the difference of potential at the brushes e and e'.

Calling e and e' the gross counter-electromotive forces, and p the effective resistance, have the equations—

$$t\frac{(e+I\,p)^2}{e}, \quad t'\frac{(e-I'\,p)^2}{e} = n\varphi^2,$$

and, as e here is equal to e', we have—

$$\frac{t-t'}{t+t'} = \frac{I^2-I'^2}{2\,e\,p},$$

$$p = \frac{e}{I+I'},$$

$$\frac{e}{I-I'},$$

and, finally, the value of e or e' or $n\varphi^2$, is—

$$e = \left\{\frac{t(t-t')}{t-t'\left(\frac{I-I'}{I+I'}\right)^2}\right\}$$

or

$$e' = \left\{\frac{t'(t-t')}{t-t'\left(\frac{I-I'}{I+I'}\right)^2}\right\}$$

FIG. 8.

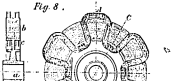

FIG. 6.

dent at the centre; no effect on the cracks; shot broke up.

No. II.—Just below crack *b*, 11 deg. from normal; slight indent as in former round; plate and cracks unaltered.

No. III.—Near crack *b*, 21 deg. from normal; as last round, small indent; plate and cracks unaltered.

These three rounds having shown that crack *b* had no injurious effect on the plate,

No. IV. was directed against crack *a* at bottom; angle to normal, 30 deg.; no result.

No. V. struck right on the centre of the crack; no result on crack or plate.

As five rounds, with a total striking energy of 1600 foot-tons, had produced no effect in widening or extending the cracks, it was shown that such superficial "chill-cracks" do not in any way diminish the strength or endurance of a plate. The trial also exhibited the high resistance of the shield, three rounds being delivered in a space of 56 square inches without producing any effect on the plate.

The trial was continued on the 19th of January, 1883.

Hitherto plates had been tested by spreading hits over the whole surface in accordance with the conditions prevailing on actual service; the object of the continued trial was to test the endurance of the plate under a series of rounds concentrated in a manner which in action could not be realised, *e.g.*, together on a small portion of the surface, and to observe in what way the clearage of the plate would be effected by such a fire.

No. VI.—Forged steel shell, weight 80 lb. Striking energy, 1220 foot-tons. Angle of impact 8 deg. from normal.

Result. Struck as in diagram, no effect on plate or cracks.

No. VII.—Forged and tempered steel shell, weight 79 lb. Striking energy, 1221 foot-tons. 48 deg. from normal. Fired against crack *a*, no result.

The remaining rounds were concentrated on the centre of the plate.

No. VIII.—Tempered steel, small cavity, shell, weight 86.5 lb. Striking energy 1323 foot-tons. 11 deg. from normal. Slight hair crack formed, 6 in. long (*e*) in diagram.

No. IX.—Same projectile. Angle of striking 12 deg. to normal. No effect on plate, hair cracks unaltered.

No. X.—Forged and tempered steel shell 85.5 lb. Striking energy 1257 foot-tons. Angle to normal 11 deg. Slight hair crack 3 in. long in bottom of (*e*).

No. XI.—Same projectile. No result, plate and cracks unaltered.

No. XII.—Same projectile. Hair cracks, *c*, unaltered. A fine crack 15 in. long formed (*d*) in diagram.

No. XIII.—Same projectile *d* lengthened to 28 in. The trial was suspended in order to procure from Austria a supply of projectiles which it is intended to test. It will then be continued.

The result so far may be considered very satisfactory. It should be remembered that the plate under trial had been rejected as faulty; moreover, being a "side" plate, and consequently not exposed in action to direct fire, it was only 17.7 in. thick, whereas the front plates of the shield, which are designed to withstand the direct attack of the 5.9-in. R. L. gun are 20.9 in. thick. The plate withstood 13 direct hits with a total striking energy of 16,000 foot-tons, without appreciable cracks notwithstanding that most of the rounds were concentrated on a small area. The crack developed by round No. VIII. remained unaltered by subsequent rounds, although X. and XI. struck right upon it, and XII. close beneath it. The hair crack *d* was so small that for a long time it escaped observation under a close scrutiny of the surface of the plate. It is not probable that it injuriously affected the shield, as experiments have shown that the production of such hair cracks, which do not reach the soft iron lying under the chilled face no influence in hastening the final destruction of the plate. Moreover the fact of the hair crack *d* crossing instead of prolonging the "chill crack" *b*, and the absence of any result from round VII., show that such cracks are in casting are not injurious.

It should be noted that 7 shots struck in an area 24 in. wide by 15 in. high with a total energy of 11,301 foot-tons. The longitudinal effect of these rounds exhibits in a striking manner the high resis-

NATURE

THE PROPER PROPORTIONS OF RESISTANCE IN THE WORKING COILS, THE ELECTRO-MAGNETS, AND THE EXTERNAL CIRCUITS OF DYNAMOS?

FOR the electromotive force

Let L be the length of the wire,

B = bulk of the whole space occupied by wire and insulation,

w = ratio of this whole space to the bulk of the copper alone (that is, let $\frac{1}{w}B$ the bulk of the copper),

A = the external area of wire and insulator,

K = the resistance of the wire.

For the working coil, let the corresponding quantities be L', B', w', K'. Lastly, let v be the specific resistance of the copper. We have—

$$B = AL \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$B' = \sqrt{w w'} B = \frac{K}{K'} B \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Hence, $A = \sqrt{w w'} \frac{K}{K'} A' = \frac{K}{K'} A \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$

and similarly, $A' = \sqrt{w w'} \frac{K'}{K} A' = \frac{K'}{K} A \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$

where K and K' denote coefficients.

Now, let r be the current through the magnet coil, and r' that through the working coil, and let v be the velocity of any chosen point of the working coil. Denoting by f the average electromotive force between the two ends of the working coil, we have—

$$f = \int \frac{1}{A'} v r \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where f is a quantity depending on the forms, magnitudes, and relative positions of B and B', and on the magnetic susceptibility of iron; divided-ring as the susceptibility diminishes with increased strength of current, or with any change of B and B' which gives increase of magnetic-ring forces.

In the simple-circuit dynamo (that is, the ordinary dynamo) r is equal to r', but not so in the shunt-dynamo. In each, the

* "On the Present Position and Prospects of Political Economy" (Dutch Association, Dublin, 1868).

† Quoted by Mr. Grant Duff, Presidential Address to Section F, 1868.

‡ Paper read at the British Association, York, 1881, by Sir William Thomson, F.R.S.

whole electric activity (that is, the rate of doing work) is fr'; or, by (3)—

$$\frac{r r'}{A' v} \int v \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

But, by (1) and (2)—

$$\frac{1}{K K'} \int v (A' E' r' + A E r) \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

Of this whole work, the proportion which go to waste in heating the coils and to work in the external circuit are—

$$\frac{A' E' r'}{K K'} \int v \quad \text{and} \quad \frac{A E r}{K K'} \int v \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

If $A' E' r' = A E r$, the ratio of (6) to (5) is a minimum, and the useful work (7) by making $\frac{1}{K}$ sufficiently great, the ratio of (6) to (5) (waste to useful work) may be made as small as we please. Our question is, how ought K and K' to be proportioned to make the ratio of (6) to (5), or the work a minimum, with any given speed v, or, what comes to the same thing, to make the speed required for a given ratio of waste to useful work a maximum? Let m be the ratio of the whole work to the waste. We have, by (3) and (6)—

$$r = \frac{A' v (E' R' r' + E r)}{E' r' R' K'} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

For the single-circuit dynamo we have $r = r'$, and (8) becomes—

$$r = \frac{A' v (E' R' + E)}{E' R' K'} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

or

$$r = \frac{A' v (E' R' + E)}{S K K'} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

where

$$S = R + \frac{K}{K'} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

Suppose now K' to be given, and suppose r for a moment I to be constant. The problem of making r a maximum with a given v, or a minimum with r given, requires simply that $\frac{K}{K'}$, the resistances in the working coil and the electro-magnet are equal. But in reality I is not constant; it diminishes with increase of the magnet-ring force. As it generally depends chiefly on the soft iron of the electro-magnet, and comparatively but little on the soft iron of the moving armature, or on lost magnetism of the current through the moving coils, it will generally be the case that I will, *cæteris paribus*, be diminished by increasing K and diminishing $\frac{K}{K'}$. Hence the maximum of r is shown by (10) to require $\frac{K}{K'}$ to be somewhat greater than $\frac{1}{S}$; how much greater we cannot find from the formula, without knowing the law of the variation of I.

Experience and natural selection seem to have led in most of the ordinary dynamos, as now made, to the resistance in the electro-magnet being somewhat less than the resistance in the working coil, which is in accordance with the preceding theory.

Whether the useful work of the dynamo be light-giving, or power, or heating, or electro-metallurgy, we may, for simplicity, reckon it in any case as done by applying to the current standard of a dynamo a resistance E in addition to the current resistance E connecting the working terminals of the dynamo. This conductor, in accordance with general usage, forms the "external circuit," which is no abbreviation for the part of the whole circuit which is external to the dynamo. In the case of the single-circuit dynamo the current in the external circuit is equal to that through the working coil and electro-magnet, or r of our notation. Hence, by Ohm's law—

$$r = \frac{A' v E'}{E K' (E + R + R')} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (12)$$

or, by (3), (4), and (2),

$$r = r_{\prime} \frac{f \sqrt{(E E')} v}{K K' (E + R + R')} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (13)$$

Hence either

$$r = 0 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (14)$$

or

$$I = \frac{K K' (E + R + R')}{f \sqrt{(E E')} v} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (15)$$

The case of $r = 0$ is that in which

$$v = \frac{K K' (E + R + R')}{L \sqrt{(E E')}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (16)$$

where I denotes the value of I for $r = 0$. To understand it, remember we are supposing that no residual magnetism. For any speed slighter to (16), the dynamo produces no current. When this limit is exceeded the electric equilibrium in the circuit becomes unstable: an infinite-small current started in either direction rises rapidly in strength, till it is limited by repulsion (15), through the diminution of I, which it produces. Thus, regarding I as a function of v, we have in (15) the equation to mathematically expressing the strength of the current maintained by the dynamo when its regular action is excited. Using (15) in (10) we find—

$$r = \frac{E + S}{I} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (17)$$

which we all have forty years ago from basic.

In the shunt-dynamo the whole current, r, of the working coil branches into two streams, through the electro-magnet, and r through the external circuit, whose strengths are inverse-ly as the resistances of those channels. Still calling the resistance of the external circuit E, we there re have—

$$r E = (r' - r) E_{\prime} \text{ which gives } r = \frac{E}{E + E'} r' \quad . \quad . \quad . \quad . \quad . \quad . \quad (18)$$

Hence, by Joule's original law, the expenditure of work per unit of time in the three channels are respectively

$$K r^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad \text{working coil}$$

$$K \left(\frac{E}{E + E'}\right)^2 r^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad \text{Coils-magnet}$$

$$E \left(\frac{E}{E + E'}\right)^2 r^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad \text{external circuit.} \quad . \quad . \quad . \quad . \quad . \quad . \quad (19)$$

Hence, dividing as above by r the ratio of the whole work to the work developed in the external circuit, we have—

$$r = \frac{A \left(\frac{E}{E + E'}\right)^2 + A \left(\frac{E}{E + E'}\right)^2 + E}{\left(\frac{E}{E + E'}\right)^2 E} \quad . \quad . \quad . \quad . \quad . \quad . \quad (20)$$

whence

$$K r = \frac{K R' E + E' E + E' (E + E)}{E} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (21)$$

$$= \frac{R' E + (E + E') E + E' (E + E)}{E} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (22)$$

Suppose now K and E' given, and $E + E$ to be found; to find r a minimum. The solution is—

$$E = \sqrt{K E'} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (23)$$

and this makes

$$r = 2 \sqrt{E'} (E + E') = 2 K + R \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (24)$$

But now

$$\frac{K}{E} = r \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (24)$$

(22) and (23) become

$$E = \sqrt{K E'} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (25)$$

and

$$r = 1 + 2 \sqrt{r (1 + r)} + 2 r. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (26)$$

For good economy r must be but little greater than unity; hence r must be very small, and therefore *approximately*

$$r = 1 + 4 \sqrt{r} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (27)$$

For example, suppose the resistance of the electro-magnet to be 400 times the resistance of the working coil—that is $r = 400$—and we have, approximately,

$$E = 20 E', \text{ and } r = 21 + \frac{1}{21}.$$

That is to say, the resistance in the external circuit is twenty times the resistance of the working coil, and the useful work in the external circuit is approximately $\frac{21}{22}$ of that lost in heating the wire in the dynamo.

ELECTRICAL REVIEW

MAGNETO-ELECTRIC APPARATUS.

Magneto-electricity—*i. e.*, electricity generated by magnetism, has of late years received much attention; and as great improvements have been introduced in the apparatus that, for certain classes of practical applications, it bids fair to supersede the voltaic cell. Through its agency mechanical energy may be transformed into electricity of almost any desired potential and quantity.

The fundamental principle upon which this mode of generating electricity depends is identical with voltaic induction. Indeed, according to the accepted theory, the phenomenon of magnetism is due to a series of electrical currents, circulating, around the molecules in a common direction, and the resultant of the effects of such a system is equivalent to that of a single current encircling some central axis.

Facing the north-seeking pole, the direction of the resultant current is contrary to that of the hands of the watch; facing the south-seeking pole it accords with their direction.

Adopting this theory, let the north-seeking pole of a magnet be inserted by successive movements into a continuous ring of wire. According to the laws of voltaic induction, an instantaneous current of electricity will be induced in the ring at every motion, their direction when looked at from the side in which the magnet is inserted being the reverse of that of the hands of a watch. Withdrawing the magnet in the same manner instantaneous currents will be excited in the same direction as that of the hands of a watch.

If the south-seeking pole be approached to or withdrawn from the ring, similar currents, but reversed in direction, will be induced. If, now, the single ring be replaced by a special coil, and the magnet be moved as before, the currents induced will be enumerated by higher potential, their direction being the same as before.

If, instead of moving the magnet, a piece of soft (unmagnetized) iron be permanently inserted in the spiral, and by rapid contacts with the pole of a magnet be successively magnetized and demagnetized, instantaneous electrical currents will circulate as before. If the poles of a permanent magnet be extended by soft iron rods, surrounded by bobbins of wire, and the armature be applied, or withdrawn suddenly, currents in these bobbins will be developed by the resulting change in the locus of maximum magnetic intensity.

Upon these fundamental principles are based all the varieties of magneto-electric apparatus, their differences consisting simply in different mechanical devices for effecting magnetic changes within or near a coil of insulated wire.

If currents of high potential are desired the coils are made of fine wire, while if large quantity is secured coarse wire is used. In either case it must not be forgotten that the *direction* of the current is very short, and that, if a continuous succession of waves is to be produced, a very rapid succession of contacts and breaks must be provided. The current will then consist of a succession of waves in opposite directions, which, however, by the aid of what is called a commutator, may, if desired, be caused to coincide in direction. Thus modified, magneto-electric currents become very similar in their effects to those of ordinary voltaic battery.

The electricity generated by magneto-electric machines has a lower potential than that given by frictional and voltaic induction apparatus; indeed, it more nearly resembles, both in potential and in quantity, the voltaic current from many cells coupled through defects of insulation in the leading wires than that obtained from the machines already described; but, on the other hand, it exerts more attention to guard against small breaks in the continuity of the current.

Magneto-electric machines may be classified according to the form in which the force is utilized. Thus, in the progress of invention, instruments were made which united (1) by a single wave; (2) by a succession of waves alternating in direction; (3) by a current more or less unvarying. It may be added, that by the device called a commutator, an alternating current may always be changed into one pulsating in a single direction, thus transferring the instrument from class (2) to class (3).

The following tabular classification, based on the foregoing analysis, exhibits the magneto-electric igniting machines in most common use:

I. Acting by single electric wave.	{	Bisquet. Jorgensen. Marcus.
II. Acting by a succession of waves alternating in direction.	{	Wheatstone. Bearsdien.
III. Acting by a continuous current.	{	Clows II., with com. added. Gramme.

It may be remarked, in general terms, that Clowes I. and II require medium tension, and Class III. low tension force; but each kind of instrument, as a rule, has peculiarities which render it important to select its type with judgment. High tension forces can hardly be used with any variety.

In order to secure a fair idea of the relative power and convenience of these several machines for different classes of practical work, the following description of them is added. It will enable the officer to select the one best suited to his needs in any special case. The dimensions refer to complete instruments belonging to the school of Submarine Mining at Willets Point, and are the results of careful measurements. The plates are designed to explain the electrical principles, not the mechanical details of the apparatus.

THE BISQUET MACHINE.

This instrument consists of a horseshoe magnet, the poles of which, prolonged with soft iron, constitute the cores of two bobbins of fine coils of very fine insulated wire, having a resistance of 9,400 ohms. A soft iron armature in contact with the ends of these cores is attached by a brass plate to a lever extending outside the case. This lever is so pivoted as to have such a short and a smart throw will separate the armature suddenly from the poles and thus create a current; induced by the change in the forces of magnetic polarity, to circulate through the coils. The current is greatly intensified by an extra quantity caused by the following ingenious device: The coils are united in series, and the circuit is extended to two terminal posts outside the case; another circuit, forming a shunt between the coils and the terminal posts, consists in part of a spring attached to the lever and moving with it. After moving a certain distance, this spring breaks the shunt circuit, thus producing a strong extra spark by the interruption of the current at its maximum. It is chiefly this spark which passes through the exterior circuit and fires the fuses.

The instrument is encased in a neat box, 18" by 12" by 9" high, the whole weighing 21 lbs. A sliding key blocks the lever when not in use, and thus guards against accidents from careless handling. A switch and two posts on the cover allow any one of five torpedoes to be fired at will.

A tension fuse possessing a decided conductivity, like those of Abel or Von Ebner, is required with this machine; and to effect simultaneous explosions it is well to select fuses nearly alike in this respect. This may be done by noting the deflections of a delicate galvanometer included with the fuse in the circuit of a small battery. Of course, fuses must be coupled in series with this class of machines, but where more than one fuse is used some other class should be selected. Torpedoes at one time adopted the Bisquet apparatus for naval uses, but ultimately decided it to be deficient in quantity—especially for submerged cables, in which electrification largely reduces the volume of the spark. It is stated that on a land line, in 1869, a fuse was fired at a distance of 300 miles by this machine.

It is not easy to establish a standard by which to compare different kinds of igniting apparatus acting by a single wave, for the reason that the instruments differ both in the quantity and the potential of the charge; and the latter element passes from zero through an unknown maximum back to zero in a time immeasurably short. If, however, fuses having a suitable conductivity are to be employed, an approximate idea of the relative power of two machines may be derived from a galvanometer measurement based upon the following principles:

If the currents to be compared be instantaneous, and the needle be so heavy as not to move sensibly during the passage of the waves through the coils, the observed swings of the needle may be regarded as the effect of blows.

In this case the mechanical work is pro-

portional to the versine of the angle of swing (α), i.e., to $2 \sin^2 \frac{\alpha}{2}$. The electrical work is measured by the product $C^2 R T$, in which C denotes the strength of current, R the resistance of the circuit, and T the time. Hence, for two currents through the same circuit,

$$C_1 = C_2 \frac{\sin^2 \frac{\alpha_1}{2}}{\sin^2 \frac{\alpha_2}{2}} \sqrt{\frac{T_2}{T_1}}.$$

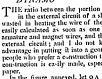
Now, if λ known wave (C_1), of such a nature that the ratio between the square roots of the two times may be assumed to be unity, be sent through a galvanometer, and its swing (α_1) be noted, and a like observation be made with the machine to be tested (giving α_2), this formula will furnish an approximate measure of the power of the latter in known electrical circuits.

This method has been applied to the Hregnet apparatus, using for the standard a known condenser charged by a battery of known potential. The latter was 828 volts. Two condensers were employed, the first having a capacity of 1,510 microfarads, and the second 2,341 microfarads. The galvanometer was a fine instrument made by Siemens Brothers, of London, and well suited to this use. The mean results of several measurements, differing but slightly among themselves, were the following:

The first charge (892 microfarads) deflected the needle 0.0 degrees.

A GEOMETRICAL CONSTRUCTION GIVING THE RELATION BETWEEN THE WASTE AND USEFUL WORK IN A SHUNT-DYNAMO

THE ratio between the portion of electrical energy utilisable in the external circuit of a shunt dynamo and the portion wasted in heating the wire of the armature and field magnet is easily calculated as soon as one knows the resistances of the armature and magnet wires, and the resistance equivalent to the external circuit; and I do not know that there is any great advantage in putting it into a geometrical form. Still there are people to refer a constant ratio to a formula, and the following construction is easily made, especially with the use of squared paper.



In the figure annexed, let O A represent the resistance of the armature between the points where the branching wires l O k are soldered on to it, and let O B represent the resistance of the field magnet wire; and O C the resistance of the external circuit, or its equivalent.

Now from B, as a diagonal, complete the rectangle O A D B, and from C, producing O C to meet B D in E.

Then if O C is equal to $\frac{1}{2}$ O E; then E G and E F, drawn parallel to O A and O B, will cut off O G and O F, which are the resistances of the two branches of the shunt.

The length H K is determined represents the waste portion of the total electrical energy, on the same scale as H O or C E represents the useful.

In the figure the effect of the armature resistance in tilting up the line C A and so increasing the waste is very manifest; the increase of waste by decreasing the resistance O A is somewhat less striking, but quite distinct; the effect of a change in O C is, as it should be, not so obvious. It may be noted that the most economical value for O C is very nearly indeed a geometric mean between O A and O B—O A; which is an easy rule to apply in practice.

Liverpool, July 19 OLIVER J. LODGE

To The Editor of Times:

SIR,—I really cannot understand how any one can find fault with gas companies, or their bills. To me, these companies seem to be the personification of uprightness and modesty, whose only aim is to accommodate the public, and have pleasant, steady rises to posterity an unblemished reputation. I get my gas from the Metropolitan-the-Company. I live in a country house between Fifth and Sixth avenues, and, as you can imagine, require a large supply of gas. Yet, looking over my bills for gas I find that for the past six years, the average is only 60l and the highest for any one year was only 68l.

Yours, truly,

A CONSUMER.

This scheme has much to commend it, it revives the drooping confidence of consumers and assumes for the gas company the role of benevolent saint. But, unfortunately, like most schemes it has its defects. A very liberal factor had been left out in the calculation. This was the liability of the bona-fide consumer to answer back, until the ridiculous tendency on the part of the consumer has, it is to be feared, completely spoiled the newspaper-letter-from-consumer-market.

Here is one of the letters brought out by the original communication:—

THE COST OF GAS-LIGHT.

To the Editor of the New York Times:

In the perusal of your paper this morning I read the article headed "Satisfied with his Gas Bills," and was surprised to hear the amount he paid yearly for gas. Living as he does in a four-story house, between Fifth and Sixth avenues, and obtaining my supply of gas from the same source—the Metropolitan Gas Company—I feel the curiosity to look over my bills for gas during the year 1882, and find they amounted to $211.06. When this "Benschcher" states that his average for the past six years is only $61, and that his highest for any one year was $68, and that at all times he had an abundance of light, this discrepancy seems unaccountable, particularly as I am living very quietly, giving no entertainments.

ELECTRICITY.

New York, Monday, Jan. 28, 1881.

Is the Dynamo a Failure?

One contemporary, *Engineering*, the leading scientific authority in Great Britain, discusses, in a recent leading article, the relative merits of electricity and gas as illuminants. After traversing the subject at some length it would seem, if we correctly interpret its meaning, to arrive at the following conclusions: 1st. That electricity, as distributed from a central Station, is far more costly than gas, and hence cannot compete with it. 2d. That the primary batteries, considered from a commercial standpoint, are, for the same reason, a failure.

It says that inventions relating to dynamo machines are no longer in demand in the city, by which it means London, and that whether the electric light can, or cannot, be supplied at the price of gas is a question which has been much discussed, and one that most people have decided must now be adjourned until the truth has been demonstrated on a grand scale. It is but, it goes on to say, difficult to estimate the expenses of an electric lighting station under certain assumed conditions, and if the lamps can only be taken up in sufficient quantities, and be burned a large number of hours each day, a very fair pro-cent can be made out.

"But everything depends upon a large and continuous consumption of current, for the annual expenses are enormously swollen by the items of interest on depreciation, and these go on whether the lights are burning or not.

This is a point, however, which is liable to escape notice, and people forget that the engines, boilers and dynamos will only be working at their full capacity, as a rule, for four or five hours a day in the Winter and never in Summer; and when a comparison is made between this form of electric lighting and others, they are apt to be led astray."

Now, without further ado, we will grant the premises adopted by our contemporary, but we must confess we find no little fault with its conclusions, which by no means tend how as a logical sequence of those premises. That is to say, granting that the "items of interest and depreciation" are more important in the electric than in the gas plant, it does not follow that the public will prefer gas to electricity as an illuminant. Those who are engaged in estimating the relative cost of producing electricity and gas are wasting their time; they are wasting the public and it is a useless search. And why? Because in a normal condition of the market, when the rebutments of gas manufacture are in active demand, carburetted hydrogen gas can be delivered to the consumer at a cost to the gas company of twenty-five cents—say a sane intensity of electricity to the consumer at such a figure. Assuredly not.

The contemporary will pardon us for the contradiction, we will assert that, under the circumstances, this person nothing at all. You can put coal tea for a tithe of what good tea will cost; you can get pinchbeck beer for less than a small part of the sum pure lager beer will cost; you can get loaded sherry and fortified wine for a mere trifle, compared with what the genuine product of the vineyard will cost. Does that make spurious tea and ale and wine to be preferred to the pure article? Does the public evince for them an amount in paid yearly for gas. Living as he does in a four-story house, between Fifth and Sixth avenues, and obtaining my supply of gas from the same source—the Metropolitan Gas Company—I feel the curiosity to look over my bills for gas during the year 1882, and find they amounted to $211.06. When this "Benschcher" states that his average for the past six years is only $61, and that his highest for any one year was $68, and that at all times he had an abundance of light, this discrepancy seems unaccountable, particularly as I am living very quietly, giving no entertainments.

ELECTRICITY.

New York, Monday, Jan. 28, 1881.

Is the Dynamo a Failure?

One contemporary, *Engineering*, the leading scientific authority in Great Britain, discusses, in a recent leading article, the relative merits of electricity and gas as illuminants. After traversing the subject at some length it would seem, if we correctly interpret its meaning, to arrive at the following

rates, while, at the same time, encouraging the use of the telegraph. Besides this, we have only the ward of the Western Union Telegraph Company to assure us that the rates are cheaper here than abroad.

In France you can send twenty words for twenty cents of our money, and the average in European countries is only one-half a cent a word. You can send twenty words from France to Algiers, a distance of two thousand miles, for twenty cents of our money. Surely, this is much cheaper than the rates which now rule in this country.

The Relentless Gas Consumer.

All else having failed them, the gas companies, with an ingenuity which those who know them will by no means be surprised at, have hit upon a novel scheme for decreasing that their charges are not exorbitants. It might not inappropriately be called the new-paper-letter-from-consumer-racket. The game is played in this wise. Here is a gas company, the meters of which are so accurate that their faces will not indicate any difference between the gas consumption in a house when the inmates are in Europe or in town, burning fifteen burners hour hour per diem. Now, let it be supposed that the Secretary wishes to manufacture a little cambric in gas consumers. He sits down at a table and writes to a morning journal a letter that reads:

To The Editor of Times:

SIR,—I really cannot understand how any one can find fault with gas companies, or their bills. To me, these companies seem to be the personification of uprightness and modesty, whose only aim is to accommodate the public, and have pleasant, steady rises to posterity an unblemished reputation. Feb. 1, 1883]
NATURE

Trial of the electro-magnetic engine, aërial screw, and bichromate elements constructed by MM. Thunmler for their directing balloon took place in their aëronautical work-shop at Point du Tour, on January 26, before a large number of electricians and aëronauts. It was shown that the twenty-four elements, each of which weighs about six kilogrammes, give during almost three hours a current which rotates a screw of 2·85m. diameter, and about 5 metres of path, with a velocity of 190 turns in a minute. The motive power really developed may be estimated at that of four horses per hour. The weight of all the machinery and elements is a little less than 250 kilogrammes. The real effect on the air can only be found by experiments in the air, but according to measurements taken with a dynamometer of the horizontal tendency to rotation, it is about the same as in the experiment tried by Dupuy de Lome. The motive power of Dupuy de Lome having been obtained with eight men working his large screw, whose diameter was 9 metres, it may be inferred that the results in the present case will be more advantageous in the ratio of *two and a half to one*. These results are not very powerful when compared with the immense power of aërial currents. But MM. Tissandier have no intention of directing their balloon against strong winds. Their object is to organise an apparatus with which universal experiments may be made in the air, and they have taken advantage of the most recent improvements of science. If their elongated balloon answer their wishes, a real advance will be registered in the history of aëronautics.

ON THE DYNAMO-ELECTRIC CURRENT AND ON CERTAIN MEANS TO IMPROVE ITS STEADINESS.

BY C. WILLIAM SIEMENS, D.C.L., F.R.S.

The author, after alluding to the early conception by Dr. Werner Siemens of the dynamo-electric or reconstructive principle of generating currents, makes reference to the two papers on the subject by himself, the one by Sir Charles Wheatstone and the other by himself, to the Royal Society in February, 1867. The machine then designed by him, and shown in operation on that occasion, is again brought forward with a view of indicating the progress that has since taken place in the construction of dynamo-electrical machines, particularly those by Gramme and Siemens and Alteneck. The paper next points out certain drawbacks to the use of these machines, both of them being subject to the disadvantage that an increase of external resistance causes a falling off of the current; and that, on the other hand, the short circuiting of the outer resistances, through contact between the carbon electrodes of an electric lamp, very much increases the electric excitement of the machine, and the power necessary to maintain its motion, giving rise to rapid heating and destructive sparks in the machine itself.

In an observation in Sir Charles Wheatstone's paper is referred to, pointing to the fact that a powerful current is set up in the shunt circuit of a dynamo-electric machine, which circumstance has then been taken advantage of in some cases, as by Mr. Ladd and Mr. Brush, in constructing current governors.

The principal object of the paper is to establish the conditions under which dynamo-electric machines worked on the shunt principle are made to give maximum results. A series of tables and diagrams are given, the results of experiments conducted by Sir Charles Wheatstone, employed at the author's works, which lead up to the conclusion that, in constructing such machines as are most applicable, the resistance on the exciting helix has to be considerably reduced by increasing the thickness of the wire employed, and that as the magnets due to be increased more than tenfold, not by the employment of thin wire, but by augmenting the length and weight of coil wire employed.

The results of this mode of distributing the resistances is summarized as follows:

1. That the electro-motive force, instead of diminishing with increased resistance, increases at first rapidly, and then more slowly towards an asymptote.

2. That the current in the outer circuit is actually greater for a unit and a half resistance than for one unit.

3. With an external resistance of one unit, which is about equivalent to an electric arc, when thirty or forty webers are passing through it, 2·24 horse power is expended, of which 1·29 horse power is actually employed, proving an efficiency of 53 per cent., as compared with 45 per cent. in the case of the ordinary dynamo-machine.

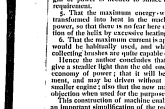
4. That the maximum energy which can be demanded from the engine is 2·6 horse power, so that but a small margin of power is needed to suffice for the greatest possible requirements.

5. That the maximum energy which can be injuriously transformed into heat in the machine itself is 1·3 horse power, so that there is no fear here of destroying the insulations of the coils by excessive heating.

6. That the maximum current is approximately that which would be habitually used, and which the commutator and collecting brushes are quite capable of transmitting.

Hence the author concludes that the new machine will give a steadier light than the old one, with greater average economy of power; that it will be less liable to derangement, and may be driven without variation of speed by a smaller engine; also that the new machine is free from all objection when used for the purposes of electro-deposition.

This construction of machine enables the author to effect an important simplification of the regulator to work electric lamps, enabling him to dispense with all wheel and clock work in the arrangement. The two carbons being pushed onward by gravity or spring power, are checked laterally by



appointed metallic abutment situated at such a distance from the arc itself, that the heat is only just sufficient to cause the gradual wasting away of the carbon in contact with amorphic ate. The carbon holders are connected at the iron core of a solenoid, of a resistance equal to about fifty times that of the arc, the ends of which coil are connected to the two electrodes respectively. The weight of the core (which may be varied) determines the force of the current that has to pass through the exciting coil in order to keep the weight in suspension, and this in its turn is dependent upon the resistance of the arc. The result is that the length of the arc is regulated automatically, so as to maintain a uniform resistance signifying uniform development of light.—*Engineering*.

THE HELIOGRAPH.

The English Government is again indebted to the Heliograph for the receipt of an important dispatch received from the seat of war in Afghanistan, announcing the result of an attack on British troops, in which their enemy suffered severely. The message was sent Camp Ghuzni, April 22d, and was received in London on the following day.

The value of the heliograph in military operations is becoming more apparent every day; in this instance the message probably could not have been delivered in time by the electric telegraph. The Heliograph does not require the route to be kept open. The line of communications can not be cut, for the simple reason that the signalling takes place over the heads of the enemy, and the stations required are few and far between.—A ten inch mirror, and this is the size of the ordinary field heliograph, is capable of reflecting the sun's rays in the form of a bright spot or flare to a distance of fifty miles, the signal at this interval being recognizable without the aid of a glass. That it is so by unwinnied eyesight, each provided with a mirror can readily speak to one another, provided the sun is shining, within a interval of fifty miles between them, provided their stations are sufficiently high, and no rising ground intervenes to stop the rays. The adjustment of the sufficient heliograph is a very simple matter.—An army lowering its heliograph as a heliograph station is located, and after travelling even a miles desires to communicate with those they have left. A hill in the locality is chosen and a sapper accords with his heliograph, which is simply a stand bearing a mirror, swung like the ordinary toilet glass, except that besides swinging horizontally, it is also pivoted, so as to also move vertically. Behind the mirror in the very centre a little of the quicksilver is removed, so that the sapper can go behind the instrument and look through a tiny hole in it towards the station he desires to signal.

Having sighted the station by adjusting the mirror, he next proceeds to set up in front of the heliograph a rod, and upon this rod is a movable rod. This rod is manipulated like the foresight of a rifle, and the sapper, again standing behind the instrument, directs the adjustment of the rod, until it is in the mirror, the rod, and the distant station are in line. The heliograph is then ready to work, and in order to flash signals, so that they may be seen at a distance, the sapper has only to take care that his mirror reflects the sunshine, on the rod just in front of him.

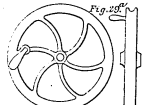
ENGLISH MECHANIC AND WORLD OF SCIENCE. No. 988. FEB. 29, 1884.

THE DYNAMO: HOW MADE AND HOW USED.—XIV.*

By SILVANUS P. THOMPSON.

§ 29. IN order to communicate the motion from the flywheel to the armature, a small pulley wheel, either of iron or brass, is fitted to the back trunnion, just outside the bearing. Such a pulley wheel may be made at any ironmonger's, and should be about 3in. in diameter, and rather over 1in. thick, with a central hole somewhat smaller than the diameter of the rod which serves for the armature trunnion. This may be attached to the trunnion in either of the two following ways:—1st. By "keying," which consists in filing the trunnion along its length, in one direction only, so as to produce a flattened side; then keying, with a rod's ball file, cleaned out the central hole of the pulley to such an extent that the said trunnion will only just enter, to deepen one side (corresponding to the flattened side of the trunnion) so as to admit of a small steel wedge or "key" being inserted (see Fig. 26). Only, by filing the trunnion rod to a slightly conical shape, and producing a similar conical "ring" in the interior of the pulley hole, which may then be driven on (see Fig. 28A, where the conical "ring" of the trunnion is exaggerated, to render this mode of attachment more plainly visible). Whichever mode of attachment is adopted, care in addition must be taken—viz., that the distance between the back of the field magnets and the pulley should not be less than 1in.; otherwise, when the limits of magnetic are wound with wire, the flywheel will run too close to them to be altogether safe.

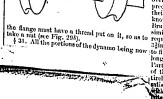
§ 30. The flywheel which gives motion to the armature, should be a pretty heavy wheel, about 24in. in diameter, with a groove in the rim to take the band which conveys the pulley, furnished with a wooden handle, for convenience of rotating. Such wheels may be obtained ready made in cast iron, from most ironmongers, as they are sent out with "rusty tiresses" for portable forges, &c. Fig. 29A gives an idea of the kind of wheel necessary, on a scale of 1in. to a foot. The central hole is turned, and only requires fitting with an iron pin, on which it turns. Since the



* All rights reserved.

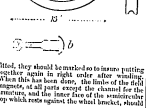
aperture in three wheels is about 3in. in diameter, the pin must be filed down to half an inch in diameter where it has to fit in the hole in the flange at the top of the dynamo.

The flywheel and should have a rounded boss to prevent the wheel from working off, while the portion which passes into the eye at the top of

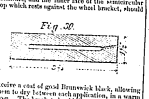


the flange must have a thread put on it, so as to take a nut (see Fig. 28B).

§ 31. All the portions of the dynamo being now



fitted, they should be marked so to insure putting together again in right order after winding. When this has been done, the brake of the field magnets, at all parts except the channel for the armature, and the inner face of the commutator, up which rests against the wheel bracket, should



receive a coat of good Brunswick black, allowing them to dry between each application, in a warm oven. The bracket should be painted on the rear or two of the same varnish, except where the semicircular bore clutch it. This portion need be left metallic, so as to insure magnetic contact; otherwise, much unnecessary leakage will be lost. Two strips of silk (before immersed) 10in. long and 1in. wide, should now be carefully brushed over with Brunswick black, and wrapped, while still wet, round the one limb, and the other round the other limb of the field magnets, at the place between the armature channel and the lead at the top. See Fig. 15, where the portions indicated by the letters respectively s and [illegible]. The object of this silk wrapping is to insulate the wire thoroughly from the iron, and to prevent any accidental abrasion of the covering wire, which may take place during the coiling round the limbs. When this has been laid smoothly and tightly on, the ends may be returned into the oven, and allowed to dry at a gentle heat. In precisely the same manner, the interior face and their central portion of the armature (to be finally turned down to the "ash") must be varnished with Brunswick black, and wrapped with one layer of similarly prepared silk. Three pieces will be required to do this effectually—viz., two pieces 20in. long by 1in. wide, shaped as in Fig. 30, to fit against the inner faces, and one piece 6in. long by 2in. wide, to wrap round the web. Particular care must be taken that every portion of the inside of the armature channel be completely covered in silk. When this has been satisfactorily performed, another coat of [illegible] black may be given [illegible] to seal the [illegible], and the armature allowed to dry thoroughly in a warm oven.

Your dynamo is now ready for wiring, [illegible] purpose we shall require about 2lb. of [illegible] cotton-covered copper wire for the [illegible] and for the armature. The smallest size useful is 20 [illegible] wire, of the highest conductivity [illegible]

April 6, 1882] NATURE 539

little volume ("A Year in Manitoba, 1880-81") is published by Messrs. W. and R. Chambers, and contains a full and concise statement of the experience of an officer and his sons on a small farm which they took ten miles from Winnipeg. There were not a few hardships certainly, and these are clearly brought out; but the other side is quite as clearly and fairly stated, with a considerable balance in its favour. For any one contemplating emigration to the Canadian North-west, this is the book to get.

Bishop Mr. O'Neill's paper on his three months' journey inland from Mozambique, the *April Proceedings* of the Geographical Society contain a *résumé* of the information just laid before Parliament on the subject of the Nyassa-Tanganyika frontier and of the Congo, accompanied by a map, which can only pretend to reproduce the Russian view of the question. The other paper describes the journey of a Russian officer from Gondokoro to the Kheddive's dominions, and is a translation from the Russian. Perhaps the most valuable matter in the geographical news is the treaty which M. Leroy-Beaulieu imposed on the Sultan of Stanley Pool, and by which they interested, to almost none but Frenchmen; some late news has been given in speaking Dr. Junker's journey in Central Africa, and Mr. J. M. Scharzer's progress to the south-west of Abyssinia. We are glad to see, too, that the international polar meteorological expeditions are not neglected, some very interesting information having reached respecting those of the Danes to Godthaab, in West Greenland, and of the Dutch to the mouth of the Yenisei. Another is also devoted to the recent Finnish expedition to Lapland, the Finns born Finns. The French Geographical Society's meetings are very fully reported, as, indeed, they generally are.

A NEW Geographical Society was formed last month at Greifswald, in Pomerania.

A CORRESPONDENT points out, in reference to Dr. Rae's correction of less weeks, that a gold medal was awarded to Nain Singh in 1877, as will be found by reference to the *Proceedings* of that year, or in the *Proceedings* cold extracts, vol. xxi. A gold watch had previously been awarded to Nain Singh in 1868, for the route-survey from Leh to Mussoorie to Lhasa.

MR. E. ARTHINGTON, of Leeds, who is well-known as the manufacturer here of Mr. Abbott's mi-meter, has just presented to the Baptist Society a further sum of 1000*l.* for the use of the Upper Congo.

THE Constantine gold medal of the Russian Geographical Society was not awarded this year; the medal at Count Lütke was awarded to Mr. Seebohm, Fairfield and Col. Lefroden, for their geological and topographical work in the Balkan Peninsula; the great gold medal of the Edinburgh Geological Society was awarded to M. Tarnuis for his explorations in North-Western Mongolia; that of the Scottish Geographical Society to Nordenskjöld, and the gold medal of the Government of Vyatka. The small gold medals were awarded to Lieutenant Schwatka, Lieutenant Lasar-ef Eastern Siberia, for his determinations of positions in Turkestan; to Lieutenant Aden to M. Hunnejhoff, for astronomical observations on board of ships; to M. Mokhatoff, for ethnographical explorations in Perm, Ural; and to M. Yadrintsef, for explorations in Northern Siberia and on the Altai." Silver medals were awarded to Mydmar L. Pahmakoloyev, for his album of photographs from Western Siberia; to M. Lakhmayer, for photographs of Caucasus and Ural; to M. Keilig, for the same between Kazan and Jekaterinburg; to M. Ivanof, for explorations of the Zeravshan glacier; to M. Agafonoff, for explorations of the black earth and Ural, in the Government of Irkutsk; to M. Rostisch, for topographical observations on the Amur; and to M. Gedyk and Jagodsky, for his works on the Caucasian languages and his biography of the well-known explorer of these languages, K. K. Gedyk; and to M. Stevenovsky and Rudinsky, for collections of Russian songs.

THE first number of the *Izvestia* of the Russian Geographical Society contains, among other interesting materials, two lists of points whose latitudes and longitudes were determined by the unfortunate explorer of Eastern Siberia and Turkestan, F. F. Sidorenkoff, the Pooyat astronomer, during the years 1879 and 1880. The latitudes were determined, in 1879, by the positions of ten points in Eastern Turkestan, he now publishes a list of twenty-four points in the Akmolinsk territory, from Sofia along the two long valleys of the Kisch and of the Kinghes rivers, which cross this territory from east to west, that of Kinghes having been explored in its source, and the most eastern point reached by M. Schwarz being the Ulutau Peak, at the south-eastern frontier of the Kirkh territory. A series of determinations between Veryni and the Issik Kul, lying along the Tekes river, were made during the same year. The numerous magnetic observations made by M. Schwarzof during these two journeys, will be published as soon as calculated.

MATTER AND MAGNETO-ELECTRIC ACTION[1]

[1] Into Prof. Clerk Maxwell, in his work on "Electricity and Magnetism" (vol. ii. p. 148), has drawn as a principle that a mechanical force which urges a conductor carrying a current across the lines of magnetic force, acts, not on the conductor as a whole, but on the conductor which carries it. If the conductor be a solid rod or a fluid it will move in obedience to this force, and this motion may or may not be accompanied with a change of position of the electric current which it carries. But if the current shall be free to choose any path through a fixed solid conductor, or through a bath of water, then when a constant magnetic force is made to act on the system, the path of the current through the conducting mass permanently alters, but after certain transient phenomena, called induction currents, have subsided, the distribution of the current is found to be the same as if no magnetic force were in action. The only force which acts on electric currents is electromotive force, which must be distinguished from mechanical force which is the subject of this chapter.

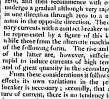
In the investigation on electric discharges, on which Mr. Stokes and myself have been long engaged, we have met with some phenomena of which the principle above enunciated throws the best light, not the only explanation. But whether they be regarded as fairly accounting out of that investigation, or as experimental illustrations of a principle laid down by so great a master of the subject as Prof. Clerk Maxwell, I have ventured to hope that they may possess sufficient interest to form the subject of my present discourse.

The experiments to which I refer, and of which I now propose to offer a summary, depend largely upon the mechanical effect of exciting an induction-coil. The method was described in two papers, published in the *Philosophical Magazine* (November, 1879, and in the *Proceedings* of the Royal Society (vol. xxx. p. 172), respectively; but as its use appears to be still mainly confined to my own laboratory, and to that of the Royal Institution, I will, with your permission, devote a short time to a description of it, and to an exhibition of its general effects.

The method consists in connecting the primary circuit directly with a dynamo-or magneto-machine giving alternate currents. In the present case, I use one of Mr. de Meritens' excellent machines driven by a Thomson-Houston gas-engine. The speed of the armature, making, as shown, about 1100 revolutions per minute.

In this arrangement the current is in the secondary coil once or alternately in a contrary direction, and in the primary, at each make, there arises a current which tends to oppose the main current, during the working of the machine, to be the case at both ends.

The currents in the primary are also alternately in one direction and in the other, but momentarily, at each make, between their value passes through zero. But they differ from those delivered in the primary coil with a direct current and current breaker in an important particular, namely, that while the latter, at breaking, fall suddenly from their strength to zero, and then recommence with equal suddenness, the former undergo a gradual although very rapid change from a maximum in one direction through zero to a maximum in the opposite direction. Roughly current-with a contact breaker would be represented by a figure of this kind, while those from the alternate machine approximately by a curve of the following form. The rise and fall of the latter are, however, sufficiently rapid to indicate a very high tension and of great quantity in the secondary.



From these considerations it follows: first, that as the machine effects its own variations in the primary current, no contact breaker is necessary; secondly, that as there is no sudden rupture of current, there is no tendency in the extra current to produce a spark or any of the inconveniences due to an abrupt opening of the circuit, and consequently that the condenser

AN IMPROVED ELECTRO-MOTOR.*

By THEODORE WIESENDANGER.

While recently many minds have been at work, with more or less of success, to produce improvements in dynamo-generators of electric energy, very few have given their special care and attention to the development of the electro-motor. Experience has taught us hitherto that the efficiencies of one and the same machine for action and reaction, or for use either as a generator, or by the inverted process as an electro-motor, stand in a certain and direct proportion to each other, or that our most efficient generators, such as the Siemens, Brush and Gramme, machines prove also the most effective motors, and on the other hand that inferior dynamo-machines invariably are inefficient motors. It would, however, be hazardous to conclude from these results that this rule should hold good for all future machines, and from the results of researches I have recently made, I come to the conclusion that the motors which are to supersede those now in use could not be employed as generators. Dynamo-machines, such as now constructed, only prove efficient when their field-magnets are able to retain at all times (*e. g.*, even when the machine stands at rest) a certain and very considerable amount of residual magnetism, and for this reason their cores are made of retentive material, hard cast iron, as is the case in the Brush and Gramme machines; or if the cores consist of soft iron they are attached to large masses of hard cast iron. In such a manner that the latter are inclosed in the magnetic circuit, and form part of the cores.

Generators of the same kind, when made small in size, have cores much larger and heavier in proportion, and, moreover, baseplate, or, as in the Weston machine, a heavy retentive cylinder, is made to form a portion of the field-magnets. But all efforts hitherto made to produce efficient small dynamo-machines with cores of soft iron only, have resulted in absolute failure, although some of the highest genius have made repeated and prolonged efforts to solve the most difficult of problems.

These curious facts conclusively prove that the theory explanatory of the action of dynamo-machines, as now universally adopted, viz., the theory of inductive action and reaction between the field-magnets and the armature, can not any longer be considered complete or satisfactory; for even wrought iron, especially when occurring in large masses, always contains an appreciable amount of residual magnetism, more especially after it has once been subjected to strong magnetization, and if the above theory were correct and complete, then the smallest possible amount of residual magnetic energy, augmented by repeated action and reaction, would be sufficient for the starting of such a machine in action. This, however, experience proves *not* to be the case, and the theory, although mostly adhered to, must be either abandoned or amended.

The inventors of the most recent electro-motive engines have worked—perhaps unconsciously)—upon the idea that the construction and action of electro-motors are based altogether upon the same laws as those of dynamo or magneto-machines, and, in accordance with that assumption, the field-magnets of the Deprez motor are made to consist of large and heavy masses of magnetized steel.

Experimenters have also for a long time past clung to the idea that the efficiency of an electro-motor—or the amount of energy to be obtained from such a machine by means of a current of given strength circulating in the coils of its armature only—bears a definite and direct proportion to the magneto-inductive power of its field-magnets, and that an increase of power in the field-magnets alone must necessarily give greater capabilities of the machine.

This, however, is a mischievous theory, because erroneous in its very principles, and development would only lead to the hypothesis of perpetual motion. On the contrary, starting from the consideration of the fact that a very small magnetic needle, if acted upon by one of the poles of another and very powerful magnet, has its polarity destroyed or reversed, and that if one of its poles, say the N pole, is presented to a similar (N) pole of the larger magnet, the former will instantly lose its characteristic qualities and be attracted by its overpowering opponent, we can only come to the one rational conclusion that the power or the field-magnets of an electro-motor, as compared to that of the magnet or magnets constituting its armature, should not surpass the limit of some certain ratio, to be determined yet by experiments carefully conducted, and that, if it surpasses the limit, the capabilities of the machine must be impaired. Acting on this principle, I have constructed a motor in which the power of the field magnets is as nearly as possible equal to that of an armature, the core of the former being very light and made entirely of soft iron; and the satisfactory results obtained from this machine are a sure sign that further investigation of the subject and experiments made with a view of determining the exact ratio of power between the magnets and armature will result in further improvement.

Another and very important consideration in the construction of dynamo-machines and electro-motors has not yet received that care and attention from scientific investigators which would lead to immediate progress. It is the method of motion of the revolving armature with regard to its approaching to, or receding from the poles of the field-magnets. In nearly all the machines now constructed the polar faces of the cores of the field-magnets and those of the armature are of such a shape, and the latter is caused to revolve in such a manner, that only in a small portion of the revolution its poles either approach the poles of the field-magnets or recede from them. But the most successful production of induced currents will be achieved, and the greatest amount of power will be derived from a motor, if attention is paid not merely to the one condition, that the armature should revolve in the most highly concentrated magnetic field possible, but also that nearly the entire motion of the revolving armature should be either one of approach or of withdrawal. Let us first of all consider the case of a machine with two poles only of field-magnets and two poles of the revolving armature.

It is usual to give the active faces of the former such a shape that a section of the same represents a portion of a true circle. See Fig. 1.

In the ordinary machines now in use the radius of the circle described by the outline of the revolving armature, and that of the larger circle described in portion by the outline of the inner or active faces of the poles are nearly the same, and the two circles are concentric. (See Fig. 2.) The poles *g f* of the armature only approaches the pole A of the field-magnets while moving *from e to d*, or where the intensity of the magnetic field of A is at its minimum. When continuing its motion *from d to e* and to *f*, the pole *g* can no longer be said to approach A, because the distance between the respective surfaces remains constant.

I therefore propose that the devices shown in Figs. 3 and 6 should be adopted. The radius of the circle, part of which is formed by the section *d, r, e*, is considerably larger than that of the circle described by the outline of the field of motion of the armature; *d, e, r* is, moreover, considerably less than the half of a circle and the three circles *d, r, e, f, r, A*, and that described by the outline of the field of motion of the armature are not concentric. The pole *g* of the armature, when in motion, approaches the pole A, not only in its course from *d* to C, but also when in the most intense magnetic field of A, viz., whilst moving from C to *s* and *f*. *Fig. 11* represents a section of the field-magnets' cores E F and G H, and pole's pieces N and S cast in one piece with cores and mounted on a base board, to which they are fixed by the two bolts R and T. The same principles may be applied to machines with field-magnets of more than two poles (see Fig. 2); or the armature itself may be made of polar faces shape as to work under the conditions above stated (Fig. 4). But even if the poles of the armature and those of the field-magnets are of the ordinary shape, a machine with more magnets will be more perfect in its action than one with two poles only. Fig. 10 illustrates a machine in which the armature during nearly the whole of its motion either approaches to or recedes from

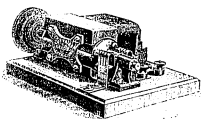
THE CUTTRISS ELECTRO-MOTOR.

ONE of the objects of interest to be seen at the exhibition now being held at Stratford is a small electro-motor, called the "Singer" sewing-machine, a description of which will doubtless interest many of our readers.

The accompanying engraving will almost



explain itself. The total weight of motor, with tools—keys, &c.—is 7lb.; the armature, "a Siemens," is 1in. diam. by 2¼in. long, which, with a current from six cells, attains a speed of about 2,000 revs. per min., when running light. The motor has been so applied to any sewing-machine, the power being transmitted to the periphery of a hand-wheel by means of a rubber friction-ring on the motor-shaft, which makes a very simple and effective means of driving.

When not required, the motor may be disconnected, leaving the sewing-machine capable of being driven in the usual way. The average speed obtained by the one under notice is 150 stitches per minute, which may be increased as required by the simple pressure of the foot upon a treadle connected with a battery of six Schumacher cells, each size being 2½in. by 2in. It need scarcely be added that the motor is capable of being applied in various ways, such as the driving of fans, light lathes, &c.

The motor, which are of various sizes, are manufactured by Messrs. Cuttriss, electricians, Leeds.

DYNAMO ELECTRIC MACHINERY.

ON Monday night Professor Silvanus P. Thompson, B.Sc., delivered the first of the Cantor lectures for the Session. Dynamo-electric machinery in the hall of the Society of Arts. Professor Thompson said that the name "dynamo-electric machine" was first applied by Dr. Werner Siemens to the magneto-electric machine in January, 1867, to the Berlin Academy. He there described a machine for generating electric currents by the application of mechanical power, the currents being induced in the coils on rotating an armature. The principle of electro-magnetic rotation which were then employed by the currents so generated. Since the great application of electric lighting it had been found convenient to use the generating machines in certain combinations in which the self-exciting principle was abandoned. The main principle of the dynamo-electric machine was the following:—If a coil of wire be rotated in a magnetic field, caused currents to be excited with those conditions. If the term was now applied, dynamo-electric machines were machines for converting energy in the form of mechanical power into energy in the form of electric currents by the operation of setting conductors in the field of force of a magnet. If a wire be made in a magnetic field. The machine might be divided into three classes. The first was that in which one pair of the coils took the place in a uniform field of force upon an axis in the plane of the coil and parallel to it. The second consisted of machines in which were was the translation of the coils to different parts of the field of force, or opposite sides of the field. The third class, which had not yet come into practice, was, we understood, a modification of the first, accompanied by an endless increase in the lines of force cut, the latter being caused by one part of the conductor sliding on or round a magnet. If he were asked what dynamo-electric machine was the best he would say that none was theoretically perfect, one might be better for one class of work and another for a different description. This being so, he might say that everything was in favour of his machine, which he was then illustrating by diagrams and by experiments. The subject of the succeeding lectures is to be the dynamo in practice and the dynamo as a motor.

DYNAMO-ELECTRIC MACHINERY.*

By Prof. S. P. Thompson, B.A., D.Sc.

(Continued from p. 625.)

Commutators, Collectors, and Brushes.

61. COMMUTATIONS and collectors being liable to defects, should be passed through inspection, and if any sparking should be made of very substantial good workmanship.

62. In the case of a collector made of parallel bars of copper, ranged upon the periphery of a cylinder, the separate bars should be capable of being removable singly, to admit of repairs and renewals.

63. The brushes should touch the commutator or

* Extracted from the Cantor Lectures, delivered before the Society of Arts.

the collectors at the two points, the centralities of which are respectively the highest and the lowest points of the circumference. In a properly arranged machine, these points will be at opposite ends of a diameter.

64. The armatures of the armature itself, when traversed by the currents, should be parallel to the magnetic lines of force of the field will not run straight across, from pole to pole of the field magnets, but will take, on the whole, an angular direction, being twisted a considerable number of degrees in the direction of the rotation. Hence the diameter of armature (which lies at right-angles to the resultant lines of force in machines of the Siemens and Gramme type and parallel to the resultant lines of force in machines of the Alliance type) will be found to be the axis of the coils which form a certain angular lead. The amount of this angular lead depends upon the relation between the strength of the magnetic field and the strength of the current in the armature coils, and this relation varies in the four different types of field-magnets. In the series-wound types of field-magnets (mostly on the other), the angle of lead is nearly constant, whatever the external resistance, the speed, and the current may be, for the reason that the same, because the variations of resistance in the external circuit do not affect the current in the field-magnet coils, and hence the variables which determine the angle of lead.

65. Hence it is not always desirable to have an adjustment, enabling the brushes to be rotated through a considerable angle, so as to suit the position of the diameter of commutation for the time being. Otherwise there will be sparking at the commutator, and a part of the energy of the current will be wasting itself by causing sparks, instead of doing electrolytic force.

66. The arrangements of the collector, or commutator, should be such, that as the brushes pass from one bar to the next, no coil or section in which there is a powerful current at the time is short circuited, otherwise work will be lost in heating that coil. For this reason, it is well to arrange the collector that the several coils are not or rule on either side of the neutral position (where the effect but very slightly is produced) from one another.

67. The number of contact points between the brushes and the collector, or commutator, should be as numerous as possible, for by increasing the number of contacts, the energy wasted in each coil will be diminished inversely as the square of that number. The brushes might, with advantage, be constructed, in each of parallel lines striped of copper, each being edgewise on the collector.

Relation of Size to Efficiency.

The efficiency of a dynamo-electric machine is the ratio of the useful electrical work done by the machine to the total work supplied to the machine for driving it. Every cause which contributes to wasting the energy of the machine contributes to efficiency of the machine. In the preceding paragraphs it has been shown what the chief electric sources of waste are, and how they may be avoided. The precautions needful to obtain foremost efficiency are also pointed out. Foremost of all is that of resistance, resistance opposing electromotive force, have been delineated. The modifications of the existing parts can be introduced also by due mechanical arrangements. But one thing cannot be suddenly altered, because even the best conductors employed have a certain resistance. We have seen that the resistance of a conductor varies, and the power wasted by that resistance varies with the square of the current. In large dynamo-electric machines, the more important dimensions remain the same. There is but one way to reduce this, and that is by increasing the size of the machines. For some dimensions we have been fundamentals of large dynamo machines, not because I have any fancy for large machines, but because I have found by experience in dynamos, the largest machines may be made more efficient than the small, and more profitable to their owner. In discussing the relation of size to efficiency, I shall assume, for the sake of argument, that the machines are similar in every respect, but in size. It is assumed that though the diameter is increased, the number of turns of wire remains the same, and that the density of the magnetic field, per square centimetre, remains also constant. If the linear dimensions be three or four times greater in the machine as in the smaller, the surface of the field-magnets will be nine or sixteen times greater, and the weight of them will be more than 27 times but greater than 64 times. If the same increase of dimensions in the coils be observed (the number of lines round of turns remaining the same as before), the length of wire on the armature will be three or four times as great, and the area of cross-section of the wire will be 9 or 16 times as great as before. The resistance of these coils will, therefore, be but $\frac{1}{3}$ or $\frac{1}{4}$ part of the original resistance of the smaller machine. The field-magnets will be magnetized to the same strength as before, and the resistance of these will be unaltered. Moreover, seeing that while the speed of the machine is the same, the arm cut through by the rotating coils is increased 3 times, these coils will in the same time cut 3 times as many lines of force, or the electromotive force will be increased 3 times. Supposing the whole of the circuit to be similarly magnified, its resistance will be 3 times $\frac{1}{3}$ of the previous value.

If its magnetism is a "series"-wound dynamo, an electromotive force will be produced 9 times $\frac{1}{3}$ or 3 times greater than before. Such a current will, therefore, work more than suffice to bring up the magnetic field to the required strength—viz., 3 times the former strength. The magnetized to the same average strength, will require excitement, as slightly more than the sum of 3 times as great, is needed to produce the same magnetic field. Here an economy may be effected, by reducing not only the number of coils, and therefore the wasteful resistance of the field-magnet coils, but also the number of turns of wire in the field-magnet coils. Even if this were not done, by the former, the machine will be improved in efficiency of a "series" dynamo, the machine working through a constant external resistance. For if the speed be increased 3 times, and the electromotive force 3 times, and the external resistance remain constant, the current will be 3 times as great as before, and the power wasted in the coils will be 9 times as great as before. But the power wasted in the small machine, and it will be 3 times as much power to drive it. It is clearly an important economy if a machine costing less than x^3 per horse-power, will do 3 times as much work for any multiple of the increased ratio of efficiency. A machine which will do 3 times as much work as another, costing 3 times as much, and which can be electrically thirty-two times as powerful a machine.

Suppose the machine to be "shunt" wound, then it produces the field of force of 3 times as great as before, and the electromotive force will require 3 times as great (or 9 times as great) that the electromotive force will require 3 times as great (or 9 times as great) that the electromotive force will require 3 times as great (or 9 times as great) that

THE DYNAMO: HOW MADE AND HOW USED.—II.

By Silvanus P. Thompson.

(Illustrated.)

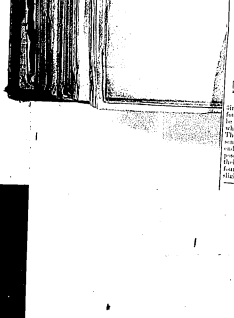
We have now succeeded in making and using a magnetic needle. In so doing we have learnt two important facts: (a) that steel becomes permanently magnetic when placed in proximity to a magnet; (b) that each pole of the new magnet thus formed attracts a polarity of opposite kind to that possessed by the pole of the original magnet which induced its magnetic condition—in other words, the end of the original magnet induces end polarity in that portion of the steel nearest to it, while the north pole induces south polarity.

Our next step is to surround the needle with a coil of insulated copper wire. To this end a piece of wood (Fig. 1), say 8in. thick, and of convenient breadth to hold in the hand, is prepared as a form, the edges being slightly rounded to admit of the wire being stripped off; this is then wound with about 100 ft. of No. 20 silk-covered copper wire, as shown at Fig. 2a, leaving about

6in. of wire projecting at each extremity. The four corners of the rectangle thus formed should be bound with silk, so as to prevent unwinding when the two ends are drawn out of the wooden form. The coil, on removal from the form, should present the appearance shown at A, in which the ends of the silk-lined hole in the centre are perfectly concentric in length, breadth, and height. The ends of the coil being finished off by means of a blunt pin (see

All rights reserved.

being taken not to disturb the silken covering), and the coil passed over the pin point pointed in the centre of the little boxwood chuck described (Fig. 2, and attached thereto with a little dab of hot sealing-wax, or better still with Prout's elastic cement. The needle is then replaced, and tried, to see whether it oscillates freely without catching at any point in the coil. The two free ends of the wire are now to be drawn out of their silk covering, cleaned with a bit of sand or glass paper, and attached to two small binding screws (those known as telephone binding screws, and sold at 6d. per dozen, will do admirably), inserted one at each corner of the base-board. The *commencement* or *outgoing* wire is now complete, in two steps or sections, from the coil to the binding-screw from which binding—as also from the *finishing* or *returning* wire—we shall presently take off the current. The commencement or outgoing wire is now carried from the binding-screw to the right-hand corner of the base-board, and there bent up at right angles, so as to form a stout upright, which is provided with a binding-screw at its top. The finishing or returning wire is carried from the binding-screw at the left-hand corner of the base-board to the right-hand corner, and there bent up at right angles, so as to form a stout upright, which is provided with a binding-screw at its top. The current-supplying wire is now connected to these two uprights, and the current is at once found to flow round the coil in the direction of the hands of a watch, when looking at the face of the dial. The coil is now placed in the centre of the base-board, so that the lower bend round each end passes north and south, and the needle will immediately start out from its position of parallelism with the coil, and take up a position which will approach nearer to right angles with the coil, in proportion as the current is stronger. To test whether the galvanometer just made is fairly dead-beat, attach a piece of copper wire about 12in. thick and 6in. long to one of the binding screws (to the other attach a similar piece of iron wire. Now bring the free ends of the wire (by bending within 1in. of each other. Turn the base-board round until the north end of the needle points between the two ends of the wire, perfectly parallel to the coil. Put a single drop of water on to a little piece of glass, and bring it under the two ends of the wires, which must be bent downwards for a inch to the shape of a gap, but not touch each other. By the action of the wire gap the current is now led, in the form of a thread of water, to the needle, which produces a second "current" which passes from the iron, down through the wire, along the copper wire, across into the iron, this action being continuous as long as the wire gap is in the iron. Simultaneously with this, the needle is seen to deflect from the line of the coil, and if our galvanometer is a perfect one, should stand out at 90° from the central line of the coil. Faraday's great discovery, on which all dynamos are based, consisted in proving that a magnet could be caused to excite a current, similar to that produced by the action of acids on metals. We can now repeat his experiment with the aid of our galvanometer. Let A, Fig. 3, be a rod of Ins.



soft iron, about 4in. long, bent to the shape of the letter U, and wound round its central portion with about 100ft. of No. 24 cotton-covered copper wire, the two ends of which (about a yard each) are left hanging loose. This U-shaped rod must be attached to the finishing screws of the galvanometer. If a good lasting current is required, the U-shaped rod should be a pair of coiled U's, the latter being kept continuous.

(31, 2.) It will be perceived that there is given a difference of only one 12in. between the Flat-Parallel and the Concave-Parallel Boards. The really correct addition, for Gamaging, to a Board of such Compass as the present, is 1 on 3in., but the 2in. has been here preferred because (among other reasons, given with *Import.* of Penal-Boards) as the nearest area of the Concave-Parall. Board in—for the sake of uniformity—adopted also for the Flat-Paral. Form, there should obviously not be, with the latter, too great a gap between the Shank and the extreme (end) Pitch Key. (All liability of the end Pitch Key to "drop out" is removed by the latter, by the author, obviated by the simple expedient of *running* the latter to *enter* into—not into the Frame Check. This latter thus being of course fully gone into in said *Department* of Penal-boards.)

(b.) It must thus be understood that the above Width for the Flat-Parallel Pedals is given chiefly as a matter of information, and that it is always best to make the *Actual* dimensions of any circuit, through which a Board is to be passed as a *fixture* in working, are such—somewhat less—as the limiting Stress will allow. If a correct guess be made (which previously must be made) for the parallel width of coil, by turning the base board round until the coil points north and south, the needle will immediately start out from its position of parallelism with the coil, and take up a position which will approach nearer to right angles with the coil, in proportion as the current is stronger. To test whether the galvanometer just made is fairly dead-beat, attach a piece of copper wire about 12in. thick and 6in. long to one of the binding screws (to the other attach a similar piece of iron wire. Now bring the free ends of the wire (by bending) within 1in. of each other. Turn the base board round until the north end of the needle points between the two ends of the wire, perfectly parallel to the coil. Put a single drop of water on to a little piece of glass, and bring it under the two ends of the wires, which must be bent downwards for a inch to the shape of a gap, but not touch each other. By the action of the wire gap the current is now led, in the form of a thread of water, to the needle, which produces a second "current" which passes from the iron, down through the wire, along the copper wire, across into the iron, this action being continuous as long as the wire gap is in the iron. Simultaneously with this, the needle is seen to deflect from the line of the coil, and if our galvanometer is a perfect one, should stand out at 90° from the central line of the coil. Faraday's great discovery, on which all dynamos are based, consisted in proving that a magnet could be caused to excite a current, similar to that produced by the action of acids on metals. We can now repeat his experiment with the aid of our galvanometer. Let A, Fig. 3, be a rod of 1in.

(c.) The additions and mod necessary by the Pedal Frame possessing a Check which is thicker than its, is easily calculated. (For the actual amount of Thickness desirable under various circumstances, see again the *Import.* of Penal-Boards.) Observe: the dimensions of the circuit have been assumed, throughout, although it is not necessary, to be 12in. wide. The Check which is 1in. thick will necessitate a Board of 13in. wide; and a fraction as taken across in the *foregoing* section; and it is equally manifest that such increase will go on augmenting as the angle of Radiation is made more obtuse, or that is to say, as the length of the Radius-line is shortened. Considering, however, that the employment of Checks of 1 inch *practical* may sometimes be contemplated, and that even if the full inch be noticed on, a very slight *paring off* of the Check corner will bring the Check thickness to the exact inch, the said precise inch is always to be made the basis of the calculation. Under my *additions* to the Check-thickness the same rule is observed; thus a Check which is 12in. thick is allowed for between the Plinth-Projections as 12in., but not more.

(d.) Three remains now the Addition by the Stances of the Frame-Check, in *Reference* Pedals, beyond the point of necessary-ment stated in the foregoing (6c., 6in. from the front-rise of the Key-Comb). This Spool will amount to from 2in. to 3in.—at each end of Circumference, according to the Angle of Radiation adopted, and by the actual length which each Check-portion extends beyond the 6in. point mentioned (see same *Import.* of Penal-Boards, Penal-mount). It will not, however, be necessary to take any account whatever, in this matter, for in all Instruments of which the Plinth is a complete Framing, and the Pedal-board is consequently obliged to be pushed horizontally through the middle of Getting for the Plinth (see at * next for a *departure* as respects such obligation, when a Side-frame is present), the question of non-fit only can arise when the said Cutting needs wider than the Pedal-Frame is at the point given,—for otherwise an unsightly *gap* will be visible after the Pedal-board has been pushed through into its place. In all Instruments, therefore, which possess a *complete* Pedal-Board, the Checks of a *Zig-zagged* Pedal-Frame (see Semitone or only Pedal-Frame) will never extend beyond the 6in. point given. (If there be Composition Pedal-pieces like the Combs for the Bearings of which is the chief object of this elongation of the Board-Check) they must be carried on a separate piece of Construction. Such separate piece is, remember, already a *necessity* even with Parallel Pedals, wherever the Pal.-Board is a *Detachable, Hinged, Folding, or Sliding* one.) In some instances the entire Pedal-Frame Redd may have to enter the Plinth one inch less Head of Pasty, by *Import.* of Penal-mounts, but the resultant gap is of too little dimension to be of practical importance.

(e.) It is necessary to consider the Concentric of the Manual with the Pedal-board. Hitherto it has been assumed that both Manual and Pedal Keys may be made of exactly the same respects right and left, of the Case, and yet a correct Path of both the Centres be obtained. This, however, is not so in fact, for it has been found by long practice and the wisdom of such a rule will be sidelined that a given Pedal Key must always be set in some exactly certain way beneath a given Manual Key,—whatever be the Compass of either the Keyboard or that of the Pedals.

This matter also is fully gone into under Head of Pasty, in *Department* of Penal-mount. It will be sufficient to say here that the *Manual* will—naturally—be always set at the exact right and left Centre of the Case Pedals; and that with a C Pedal-board either the CC or the CC sharp Pedal Key (preferably the latter) should be caused to fit directly beneath the Middle C of the Manual.

h. In order to aid to the utmost the correct Setting, Pedals, Manuals, and Stances, I especially the fundamental Pin of the Case as a whole—I here subjoin the exact amount of the divergences of Pedal-board from central path,—, which divergences have to be accommodated in the determination of the spaces which shall exist between the Front Projections of the Pedals. As the Manual is in all cases considered to be made to Normal Scale (*see Department of Manuals*).

i. With the Compass and Scale of the Pedals being as already understood, (at end of work), and the Pedals, Form of Board adopted, the Dimensions of the Pedal Circles will be as follows:—

With the Pedals placed C under G, and the Manual extending from CC to F' (Two Oct. and a Fourth), the Pedal-board will be 1in. too far to the *left*. This will small-ly interfere that the space between the Plinth-Projections be extended to double this amount; as a gap of 2in. will appear on the *right* of the Pedal-Frame.

If the F-sharp and G'in added to the top of the Manual, the latter, and of course the Pedals and the left hand Projection of the Plinth with it, will be driven one half of a Manual-Natural Key-distance still further to the left; and this will necessarily involve the setting of the right-hand Plinth-Projection at a half of such Key-distance to the *right*. Thus the dimension of 2in. will have to be added to the previous amount, making the clear length-distance between the Plinth-Projections to be 12in. full more than is required for the actual entry of the Pedal-Frame, and involving a gap of 2in. and 12in. full at the right hand of the said Frame.

k. If the Pedals be placed C sharp under G, the left-hand Plinth-Projection will obviously be driven 12in. yet more to the left; and the right-hand Projection must consequently be set the same amount to the right. Thus there is likewise involved an addition of 2½in. to either of the two previously given dimensions for C under G.

l. With the Stance of the Pedals set as already understood (at end of work), and the Pedals, Form of Board adopted, the Dimensions of the Pedal Circles will be as follows:—

With the Pedals placed C under G, and the Manual extending from CC to F' (Two Oct. and a Fourth), the Pedal-board will be 1in. too far to the *left*. This will small-ly interfere that the space between the Plinth-Projections be extended to double this amount; as a gap of 2in. will appear on the *right* of the Pedal-Frame.

If the F-sharp and G'in added to the top of the Manual, the latter, and of course the Pedals and the left hand Projection of the Plinth with it, will be driven one half of a Manual-Natural Key-distance still further to the left; and this will necessarily involve the setting of the right-hand Plinth-Projection at a half of such Key-distance to the *right*. Thus the dimension of 2in. will have to be added to the previous amount, making the clear length-distance between the Plinth-Projections to be 12in. full more than is required for the actual entry of the Pedal-Frame, and involving a gap of 2in. and 12in. full at the right hand of the said Frame.

k. If the Pedals be placed C sharp under G, the left-hand Plinth-Projection will obviously be driven 12in. yet more to the left; and the right-hand Projection must consequently be set the same amount to the right. Thus there is likewise involved an addition of 2½in. to either of the two previously given dimensions for C under G.

l. With the Stance of the Pedals set as already understood (at end of work), and the Pedals, Form of Board adopted, the Dimensions of the Pedal Circles will be as follows:—

With the Pedals placed C under G, and the Manual extending from CC to F' (Two Oct. and a Fourth), the Pedal-board will be 1in. too far to the *left*. This will small-ly interfere that the space between the Plinth-Projections be extended to double this amount; as a gap of 2in. will appear on the *right* of the Pedal-Frame.

If the F-sharp and G'in added to the top of the Manual, the latter, and of course the Pedals and the left hand Projection of the Plinth with it, will be driven one half of a Manual-Natural Key-distance still further to the left; and this will necessarily involve the setting of the right-hand Plinth-Projection at a half of such Key-distance to the *right*. Thus the dimension of 2in. will have to be added to the previous amount, making the clear length-distance between the Plinth-Projections to be 12in. full more than is required for the actual entry of the Pedal-Frame, and involving a gap of 2in. and 12in. full at the right hand of the said Frame.

k. If the Pedals be placed C sharp under G, the left-hand Plinth-Projection will obviously be driven 12in. yet more to the left; and the right-hand Projection must consequently be set the same amount to the right. Thus there is likewise involved an addition of 2½in. to either of the two previously given dimensions for C under G.

THE DEVELOPMENT OF THE PACINOTTI RING.

In our last number we had the pleasure of bringing before our readers Hulsebrink's new dynamo-electric generator, in which he employs the now classic ring armature, and, as we said on that occasion, it is rather remarkable that the most successful dynamo machines at present in use are all based on the principle of the armature ring-armature first applied by Dr. Antonio Pacinotti, of Florence, in 1860, which was first described in the *Nuovo Cimento*, which can be seen at the British Museum Library. We shall now, in this article, show the next improvement in the ring armatures in use, and Figs. 3c, 3d, 3e, 3f, 3g, 3h, 3i, 3j, 3k, 3l, 3m, 3n, 3o, 3p, 3q, 3r, 3s, 3t, 3u, 3v, 3w, 3x, 3y, 3z, 3a, 3b,

THE BRUSH SYSTEM OF ELECTRIC LIGHTING.

By CHARLES F. BRUSH, M.E.

The Dynamo-Electric Machine.

THE most prominent peculiarities of the Brush dynamo-electric machine are embodied in the armature, the arrangement of field magnets, and the commutator. The armature consists of a flat ring of soft cast iron, revolving in its own plane. Upon the periphery of this ring are a number of projections, or masses, of iron, insulated from each other, all in such a manner as effectually to prevent the formation of any complete circuit of iron around which when it is revolved in a magnetic field. On this ring are wound eight ribbons of armature conductor, whose places radiate from the axis of rotation. The ribbons are wound in the same direction, and each lies in the plane of the armature. The ends of its conductor are exposed to the direct inductive influences of the magnets. This arrangement of armature and magnets differs radically from that adopted in the Gramme machine, the only other machine of any commercial importance in which armature conductor is employed in which the conductor exposes polarity as applied to dynamo-electric machines. The armature is composed of a large number of thin plates of soft annealed iron, each insulated from the others by a thin coating of paper, and held together by two polished bronze heads. Each of these laminæ is punched with eight slots, and would have in this condition eight projecting masses of iron, corresponding to the eight slots of the armature, which would be magnetized by induction from the field magnets. To avoid this, and to secure the greatest possible efficiency of the armature, each plate is punched with eight additional slots, which are so placed as to bisect the projecting masses of iron, and thus to divide each of them into two parts. The armature is then built up of these plates, with the slots in each plate exactly opposite those in the plate next to it, and the eight ribbons of armature conductor are wound in these slots. The armature, when built, is in the form of a cylinder, with eight longitudinal slots in its surface, in which the armature conductor is imbedded. The ribbons of wire are wound in the same direction, and each lies in a plane at right angles to the axis of the armature. The ends of the ribbons are connected to the commutator (the contrivance in the dynamo-electric machine for changing the direction of the current which is generated in the armature), in such a manner as to form a continuous circuit around the armature, in which the electromotive forces generated in the several ribbons are added together. The commutator is composed of a number of copper bars, insulated from each other by sheets of mica, and held together by a metal ring at each end. The ends of the armature conductor are connected to the commutator bars in such a manner as to form a continuous circuit around the armature, in which the electromotive forces generated in the several ribbons are added together. The commutator, corresponding to the number of armature ribbons, has eight bars, and is so placed upon the shaft with reference to the field magnets, that each bar is in contact with the brush when the plane of the armature ribbon connected with it is at right angles to the lines of force, and each armature ribbon is thus commutated when it is in the position in which it is most powerful, and when no current is developed in it by its passage through the field magnets. The commutator, corresponding to the number of armature ribbons, has eight bars, and is so placed upon the shaft with reference to the field magnets, that each bar is in contact with the brush when the plane of the armature ribbon connected with it is at right angles to the lines of force, and each armature ribbon is thus commutated when it is in the position in which it is most powerful, and when no current is developed in it by its passage through the field magnets. The commutator is constructed with great care, and is one of the most important parts of the machine. Each bar is insulated from the shaft and from the adjacent bars, and is connected to the armature conductor at the proper point. The brushes which collect the current from the commutator are made of fine copper wire, and are so placed as to touch the bars when the armature conductor connected with them is in the position of most powerful induction. The brushes are supported upon a brass arm, which can be moved around the commutator, and secured in any position. The position usually adopted is that in which the brushes are in contact with the bars when the armature conductor connected with them is in the plane of the lines of force. In this position the current developed in the armature ribbons is directed entirely around the armature, and does not pass across from one brush to the other. The brushes are connected with the binding screws on the base of the machine, which are connected with the external circuit.

The Field Magnets.

The field magnets are of cast iron, and consist of two parts, the base and the cores. The base is a single casting, and consists of a flat bed, with two upright projections, which support the ends of the cores, and which are bored out to receive the bearings of the armature shaft. The cores are also castings, and are secured to the base by screws. The pole pieces are of cast iron, and are secured to the cores by screws. The coils of insulated copper wire which surround the cores are wound upon bobbins, and then drop over the cores, and are secured in place by the pole pieces.

The Commutator.

The commutator, which is one of the most important parts of the machine, consists of a number of copper bars, insulated from each other by sheets of mica, and held together by two metal rings, one at each end. The ends of the armature conductor are connected to the commutator bars in such a manner as to form a continuous circuit around the armature, in which the electromotive forces generated in the several ribbons are added together. The commutator, corresponding to the number of armature ribbons, has eight bars, and is so placed upon the shaft with reference to the field magnets, that each bar is in contact with the brush when the plane of the armature ribbon connected with it is at right angles to the lines of force, and each armature ribbon is thus commutated when it is in the position in which it is most powerful, and when no current is developed in it by its passage through the field magnets. The commutator is constructed with great care, and is one of the most important parts of the machine. Each bar is insulated from the shaft and from the adjacent bars, and is connected to the armature conductor at the proper point. The brushes which collect the current from the commutator are made of fine copper wire, and are so placed as to touch the bars when the armature conductor connected with them is in the plane of the lines of force. In this position the current developed in the armature ribbons is directed entirely around the armature, and does not pass across from one brush to the other. The brushes are supported upon a brass arm, which can be moved around the commutator, and secured in any position. The position usually adopted is that in which the brushes are in contact with the bars when the armature conductor connected with them is in the plane of the lines of force. In this position the current developed in the armature ribbons is directed entirely around the armature, and does not pass across from one brush to the other. The brushes are connected with the binding screws on the base of the machine, which are connected with the external circuit.

It will now be seen that only one pair of armature ribbons is out of the general circuit at one time, and that the number of armature ribbons in series in each section of the circuit between the points of attachment of the brushes to the armature, and are not in multiple arc, with relation to the general circuit. Now, if it were not for the "insulation" above described, the idle bobbins would afford an easy passage for the current that is in the active bobbins, and thus destroy the efficiency of the machine.

The Operation.

The operation of the commutator, which is employed for the purpose of changing the direction of the current developed in the armature ribbons, is as follows: The brush, moving from the position in which it receives the current from one of the armature ribbons, comes in contact with the bar which is connected with the next ribbon in advance, and thus establishes a circuit from one of the terminals of the machine, through the armature ribbon, and thence to the

Total power developed with the 16-light machine at 775 revolutions "closed" ..... 18·73 H.-P.
Less friction load of engine "light" ..... 2·11 "
Less friction due to increase of load (19·73—2·11 = 17·62) at 5 per cent. ..... 0·81 "
Total power consumed by 16-light machine at 729 revolutions "closed" ..... 15·81 "

Total power developed with the 16-light machine at 775 revolutions "open" ..... 4·23 "
Less friction load of engine "light" ..... 2·11 "
Less friction due to increase of load—(4·23—2·11 = 2·12) at 5 per cent. ..... 0·05 "
Total power absorbed by 16 light machine at 729 revolutions "open" ..... 1·70 "
Total power consumed by 16-light machine at 729 revolutions in the production of current (15·81—1·70) ..... 13·73 "

Note.—The terms "closed" and "open" refer to the external circuit of the machine. Thus when the machine was "closed," the current was working through the normal external resistance—the sixteen lamps. When "open," no current was generated.

These results agree very well with those obtained by other engineers with other machines of the same normal style. On February 6, 1878, Mr. Schuyler Hatton, of the Lowell Water Power Co., measured the power absorbed by one of these machines, which maximum tested in the Merrimac Print Works, and found that it required 2·5 H.-P. for the unexcited machine, and 7·5 H.-P. when the machine was operating sixteen normal lights, and the total power absorbed under these circumstances was found to be 11·93 horse-power, including friction of large pulleys and belts.

On March 26, 1878, another machine was measured at the Franklin Institute, Philadelphia, Pa., by Mr. Charles Bullock, Jr., and Mr. Leo Daft, of the Bullock-Daft Engine Co., of New York. Mr. Bullock employed the method of indicator diagrams, and obtained as a result 13·5 horse-power for the total power absorbed in the production of the sixteen lights. The speed of the machine was 1,200 revolutions per minute, and the total number of revolutions per minute of the two armatures (which was the speed at which the machine should run) was 2,400.

The higher results obtained by Mr. Bullock are probably due to the exact speed at which the machine was driven, and the abnormal friction at the journal bearings of the engine.

Referring to the experimental measurements already recorded, we find that we have a resistance of 1·5 ohms, with a total electromotive force sufficient to give the value in foot-pounds of any current in C.G.S. units. The total resistance in the circuit is 9·62 ohms. The total resistance in the circuit in ohms, the time in seconds, and the current in amperes, the product of one value per second by the other gives the energy value in foot-pounds per second. Hence, the energy from the total-circuit machine is found as follows:

$$9{\cdot}62 \times (4{\cdot}16)^2 = 9{\cdot}62 \times 17{\cdot}30 = 166{\cdot}42 \text{ foot-pounds per second.}$$

$$166{\cdot}42 \times 746 = 124{,}153{\cdot}32 \text{ ergs per second.}$$

$$124{,}153{\cdot}32 \times 10{,}000{,}000 = 1241{,}053{,}200{,}000 \text{ ergs per second.}$$

$$1241{,}053{,}200{,}000 \div 746 = 1{,}663{,}610{,}455 \text{ foot-pounds per second.}$$

$$1{,}663{,}610{,}455 \div 33{,}000 = 50{,}412 \text{ horse-power.}$$

Again,

$$\frac{16 \times 746}{33{,}000} = 0{\cdot}3618$$

horse-power required to drive the sixteen lamps, 72·9 per cent. of the total power applied in the motive power of the machine was converted into current. We have also found that 50 per cent. of the current was converted into light. Multiplying these two percentages together, we have 36·45 per cent. as the percentage of the total driving-power appearing in the arcs.

The other frictional and resistance of air-friction are power absorbed, and consider only the power actually employed in the production of current, as usually done in determining the efficiency of dynamo-electric machines, we have

$$\frac{16 \times 746}{19{,}773} = 0{\cdot}6039;$$

or 60·39 per cent. of the absorbed power converted into current. As before, 50 per cent. of this current appearing in the arcs, we have $0{\cdot}50 \times 0{\cdot}604 = 0{\cdot}302$ per cent. of the power absorbed in the production of current, present as heat and light in the sixteen arcs.

RECAPITULATION.

Resistance of dynamo-electric machine	1·05 ohms.
Resistance of external circuit	7·26 "
Total resistance of circuit	8·31 "
Resistance of 16 volatile arcs	1·00 "
Total resistance of circuit available for external work	8·31 "
Percentage of current appearing as heat and light in the volatile arcs	84·02
Electro-motive force of current	42·042 volts.
Volume of current	10·01 webers.
Energy of current expressed in foot-pounds	17·62 H.-P.
Deduct power absorbed by production of current	1·74 "
Energy of current expressed in horse-power	15·88 "
Percentage of gross power converted into current	72·90 "
Percentage of absorbed power converted into current	89·93 "
Percentage of gross power appearing in arcs	49·24 "
Percentage of absorbed power appearing in arcs	59·79 "

These results require no comment. Their excellence is apparent. They have not yet been surpassed by those of any other dynamo-electric apparatus operating multiple lights; or even by those operating single lights.

The following results are excellent "Recent tests of the Brush system of electric lighting," printed London Nov. 1, 1878, Mr. Brush's machine, of advanced power upon any in the electric lamp, in the cases of four dynamo-electric machines. The lowest result given was 84·02, the highest 87 per cent., the latter with a machine of Mr. Brush's own. This is much the highest efficiency we have yet seen reported authentically of any dynamo-electric machine, and it has been obtained only under the most favorable circumstances, as pointed out by Mr. Schwendler, with a machine fitting it single light, and developing a large volume of current (270 webers) of a comparatively low electro-motive force.

The Brush machine, developing a much smaller volume of current, and a much higher electro-motive force, and operating sixteen lights, yet shows a much higher efficiency, 84·02 per cent.

From the peculiar nature of the Brush system of lighting, it is very important advantages over other systems, not yet touched upon. We refer to the great variety in the lights which may be employed in connection with the dynamo-electric machine, and the small loss of effect occasioned by change.

When a separate dynamo-electric machine is employed for each light, according to the system which appears to be most in favour in England and France, the failure of any one machine involves the extinction of one light. Hence, in these countries a lamp must be independently regulated, with the object to keep the supply of current consumed by the resistance of the arc of consistency, and not upon each single lamp. There are, therefore, many complete sets of conductors as there are lamps.

In the Brush system, one pair of conductors is sufficient for all the lamps, no matter what their number may be; and the loss due to these conductors falls not on each lamp, but is equally divided between all. Hence, in order to maintain each light due to the conductors in the circuit, it is only necessary to add to the power of the machine in the multiple-light system, the current due to the conductors in the circuit, and that is very small. And, since the multiple-arc system requires as many sets of conductors as there are lamps, while the multiple-light system requires but one set of conductors, the total weight of conductors required in the former system, for keeping the total loss of effect due to this cause the same in both systems) bears a relation to the multiple-light system to the square of the number of lamps for the single-light system. To illustrate: Suppose sixteen lights are operated at a given distance from the dynamo-electric machine or machines, and the loss of effect due to resistance of conductors is limited by a certain amount, and let the weight of conductors required in the multiple-light system be represented by 1, then the weight of conductors required in the single-light system would be $16 = 256$. Hence, in operating a large number of lights at a long distance from the source of power by the single-light system, either an enormously expensive system of conductors must be employed, or else a great part of the whole energy of the currents will be wasted in overcoming the resistance of the smaller conductors.

This objection to the single-light system in fatal when any considerable separation of the machine and lamps becomes necessary.

The main system of lighting being free from this defect, the lights may be maintained at a great distance from the source of power with very little loss of effect, and by means of conductors of moderate and inexpensive size. For example, No. 10 (B&S gauge) copper wire measures nearly in about 0·6 ohm per thousand feet; therefore 1,000 feet of such a conductor will equal in resistance only one of the sixteen lamps already described:

$$\frac{1{,}000}{0{\cdot}6} \times 1{\cdot}5 = 1{,}666 \text{ feet.}$$

1,666 feet of such conductor would be exercised by breaking through such a conductor more than 11 miles in length (11·3611), and this loss might be lessened one-half by doubling the size of the conductor, which would still be of very inexpensive dimensions.

No reference has yet been made to the arc of more than sixteen lights. The machine No. 7 will operate over 100 arcs; but 17 or 18 lamps are often employed with the machines running at its normal speed of 720 revolutions per minute, and with good effect, although the total light produced is less than with sixteen lamps. At the speed at which the above recorded measurements were made, viz., 729 revolutions per minute, twenty lamps may be burned with tolerably good effect, although the maximum amount of light is obtained with sixteen lamps.

At any rate, thirty-three lamps have been operated simultaneously in the circuit of a No. 7 machine running at a speed of 850 revolutions per minute. The current was somewhat irregular in such lamps, but the total light produced was less than half that obtained when the machine was driven at its normal speed. If the number of lamps operated by the No. 7 machine, running at full speed, is reduced below sixteen, the brilliancy of the remaining lights is of course increased, but not in proportion to the reduction in number. Hence the full amount of light is diminished. The quantity will be increased by the current as much as to produce the maximum effect of the arc.

At the time Mr. Hollister measured the power required to drive the six-light machine, he also ascertained that required by a six-light machine of the new and style known as "No. 5."

This machine furnishes six beautiful light in single circuit, similar to those of the No. 7 machine, but with somewhat shorter arcs. (It will be remembered that the No. 7 machine was since altered to several new forms.) The total power required to drive the machine at its normal power was Mr. Hollister's figures:

Total power developed with the 6-light machine at 952 revolutions "closed"	7·13 H.-P.
Less friction load of engine "light"	2·11 "
Less friction due to increase of load (7·14—2·11 = 4·79) at 5 per cent.	0·24 "
Total power required by 6-light machine	4·79 "

No measurements of the current from this machine were made.

Remarks.

Much has been written by eminent electricians and others as to the enormous loss of total light, efficiency of arc, when the use of more than one light is made of the current from a single machine. It is true that the total light diminishes as the number of lights increases; others that the total light per arc is one of the number of lights.

These extraordinary assertions are made without any reference to the energy or character of the current employed, and are never supported by any exact measurements.

The experiments of the writer have uniformly shown that when a small amount of electrical energy is expended at several points, very little or no light results; while if the same energy be properly expended at one point, a large amount of light may be obtained. On the other hand, when a large amount of energy is properly expended at a number of points not too great, the total light produced may nearly equal that obtained when the whole energy was concentrated at one point.

A certain amount of energy is required before the light will fall to produce, and if the division falls below this, nothing in the way of light results. But after this point is reached, at which a good light is produced, then the increased light appears to be almost directly as the number of lights employed in the arc, the length of the latter remaining constant. Mr. Schwendler's experiments have appeared to coincide with our own, as he expressly declares, he says: "If the main current be divided into several branches, that the resistance of an arc of constant length is nearly proportional to the current which passes through them the light produced would be proportional to the current. This appears to be the case." Again he says: "Although the light must be nearly proportional to the total energy consumed by the whole number of lights, it is almost always the case that the current is reduced that the light is not nearly proportional to the number of the current."

It is argued by many that an increase of energy in the arc causes a corresponding increase of temperature in the crucen, and that, according to the laws of heat, the light will be more intense and better than the temperature. But, in fact, when certain point is reached, the temperature of the positive or light-giving carbon does not increase with increase of current, but the area of surface heated to maximum increases almost directly with the current. The "certain point" several times mentioned is that at which the volatilization of the carbon takes place over a considerable area on the positive carbon. Obviously, when rapid evaporation has commenced, the temperature of the carbon cannot be increased in that point, and an increase in the amount of heat evolved can only result in an increase in the rapidity of vaporization, and in the area of surface heated.

A careful study of the volatile arc, and of the carbon points after being used with currents of various strengths, cannot fail to convince the unprejudiced of the truth of these assertions.

Quite contradictory to the spirit of these portions of Mr. Schwendler's report already quoted, he says in another place: "The light of the arc is found to be almost in the same circuit by the same current, the external or available light becomes rapidly greater with increase of the number of lights attached. For this reason already, if not for many others, the division of light must result in an engineering failure."

Here we recently results that Mr. Schwendler has apparently established the fact that a current expending a given amount of energy, and adapted to produce the maximum light from one center, may, by having its dimensions radially reduced, have its cross-section increased and its volume diminished, while the energy remains the same, be adapted to produce its maximum light from several small centers, retaining the same total energy expenditure, and the energy of each center is not reduced below the "certain point" before defined. Yet he seems to be unconscious or entirely ignored this fact.

The performances of the No. 7 Brush machine, with its sixteen lamps thereby detailed, proves unquestionably that the division of a large current energy among many lights in the same circuit, or, more properly, the multiplication of lights on a single circuit, has resulted in a great engineering success.

The victories of the single-light system would advocate in place of the No. 7 Brush machine, the use of sixteen small machines, with their costly system of conductors. Each of these would require as much attendance and as frequent repairs as would be required by the single machine. At least 50 per cent., and probably 100 per cent. of the driving power would be required to produce the same lights of the same size, and the first cost of the separate machines would be vastly greater. Further, if the lights were required at any considerable distance from the source of power the single-light system must prove entirely impracticable.

Since writing the above, a later machine than the

English Mechanic & World of Science, p. 115, 1882.

GRISCOM'S DYNAMO-MACHINE.

WE have previously given general descriptions of Griscom's little dynamo-machine, which has, however, been chiefly exhibited as a motor driving sewing machines, lathes, &c. Some improvements have been recently patented in this country, and the descriptions, with the illustrations, will afford useful information to those who wish to construct small dynamos or electric motors. The invention relates to improvements in armatures for magneto-electric and dynamo-electric machines and motors, and has especial reference to armatures of the type known as Siemens; but it is applicable to the poles of all other magnets or armatures. It consists in dividing the bipolar circumflex of such armatures into two or more sections concentric with each other, one or more of such sections being at such a distance as to utilise the magnetic lines of force which fill the space between the two poles of the field-magnets, whilst the other section or sections are arranged so as to pass in close proximity to the poles of the field-magnets, and thus utilise the powerful attraction between the poles of the armature and magnet as the one approaches the other.

Figs. 1 and 2 represent a transverse section

FIG. 1

FIG. 2

of a magneto-electric dynamo or electro-magnetic armature and its field-magnet constructed according to the invention. Referring to Fig. 1, A is an armature of the before-mentioned type having its bipolar circumflex divided into two or more sections concentric with each other, one or more of which, as shown at M revolving or working at such a distance within the field-magnets B and C (see Fig. 2) as to utilise the magnetic lines of force which are generated and disseminated in the magnetic field or space between the two poles of the magnets.

The other section or sections P before referred to, are longitudinal ribs or projections concentric with, but extending or protruding above or beyond, the peripheries of the other sections M, so as to bring the whole armature in revolving, in close proximity to the poles of the field-magnets B and C therein. Between X, so as to concentrically utilise the lines of magnetic force between the poles of the field-magnets. The interior surfaces of the field-magnets B and C are formed or provided with projecting ribs or pieces arranged so as just to clear the projections P upon the armature A when it is revolving. In this manner the poles are caused to utilise certain magneto- or electro-inductive influences upon the extremity over approach of lines of force, while the polar surfaces are arranged so as to utilise the powerful lines of force existing between the magnetic field of the magnets B and C. The form and symmetry of size applied to the armature and field-magnets obviously depend on the dimensions of the machine to a certain extent, and absolutely only on the resistance, &c. The best size and form of parts we will therefore be a matter of calculation and experiment; but possibly some of our readers may even give the results of practical trials.

DYNAMO-ELECTRIC MACHINERY.—V.

By Prof. S. P. Thompson, B.A., D.Sc.

(Continued from p. 675.)

Armatures.

THE armatures or dynamos of the first class may be roughly classified in three groups, according to the manner of arranging the coils. These three groups are—

(1.) *Ring armatures*, in which the coils are arranged round a ring, whose principal axis of symmetry is the axis of rotation.

(2.) *Barrel armatures*, in which the coils are wound longitudinally over the surface of a drum or cylinder.

(3.) *Tide armatures*, having coils wound on separate pole-pieces, projecting radially round the periphery of a circular central hub.

(To these we shall add a fourth form, namely,

Disc armatures, in which the coils are flat, and lie in one plane, parallel to the face of the disc.

In all of these armatures the individual coils occupy a diametrical space, and when there is a cylindrical core, but the mode of connecting up the separate diametral sections is not the same in all. In the older of the Alliance-Siemens windings the sections were not connected together symmetrically, but in succession (for an eight-part reflector) being on the plan first in the more recent machines a symmetrical plan has been adopted, as shown in Fig. 20.

FIG. 20.

Alliance-Siemens Winding (new).

In this system, as in the Gramme ring, the successive sections of coils ranged round the armature are connected to successive bars of the collector. Each section and the beginning of the next being both united to one segment or bar of the collector. A symmetrical arrangement is, of course, preferable, not only for ease of construction, but because it is important that there should never be any great difference of potential between one segment of the collector and the next. In the present case this effect will be produced feebly at each, and force pass across the intervening gap. In Edison's modification of the drum-armature, the winding, though symmetrical in one sense, is singular, inasmuch as the number of sections is an odd number. In the first machines there were seven poles, as shown in Fig. 21. In his latest machines the number

FIG. 21.

Edison's Winding.

of sections is forty-nine. One consequence of this peculiarity of structure is that if the brushes are set diametrically opposite to one another, they will not pass at the same instant from one coil to the next, but from one coil to one which will be shortcircuiting one of the sections, whilst the other is at the middle or the opposite collector. The armature of those kind of Edison's dynamos, which is not wound up with wire, but, likewesise of Siemens's electro-plating machine, has a number of bars or blocks of copper arranged around the periphery of the core. The coils are symmetrical arcs by washers or disks of copper, insulated from each other, and having projecting lugs, to which the copper bars are attached. Each bar thus connects the terminal arcs from more straight coils. The connections are made in the following order:—Each of the forty-nine bars of the collector is connected to one of the forty-nine discs at the anterior end of the drum, which is connected by a lug-piece on one side to one of the ninety-eight copper bars. The current proceeds in this bar near to the further end of the machine, enters a disc at that end, crosses the lugs, and returns along a bar diametrically opposite that along which it started. The anterior end of this bar is attached to a lug-piece of the next disc to that which received the current, and the current thus crosses this disc to the lug to which the coil is attached, and so round again. The two lug-pieces of the individual discs at the anterior end are, therefore, not exactly opposite each other, diametrically, as the consecutive advance through $\frac{1}{49}$th of the circumference at each of the forty-nine discs.

Before passing on from the subject of armatures it is worth while to mention the peculiarity of form of the Hopkinson armature, which has already been spoken of as consisting of eight, or in the newest Hopkinson machines, as constructed by Mr. R. E. Crompton, of ten rings, set side by side. Each ring is built up of thin annular plates of iron, separated by open light metal spaces, which meet the centre of the hexagon. Over this hexagonal frame-work coils of covered copper wire are wound, being thicker at the six points intermediate between the spokes, thus making up the form of each ring to nearly a circle. Each of the six coils is separated from its neighbour by a space of $\frac{1}{6}$th of the circle, and each $\frac{1}{6}$th of the circumference in advance of its neighbour, so that the six separate coils are in fact arranged equidistantly and symmetrically, as viewed from the end round the axis. There is, however, a slight defect in which is unsymmetrical, and which is of importance, and that is that the coil that is one-sixtieth in advance—that is, to the anticlockwise coil of the next ring. The armature has the great practical advantages of being easy to construct, light, and with plenty of ventilation.

In the Elphinstone-Vincent dynamo there is a three-armature of a somewhat ballet order, the separate coils being made of a rectangular form, and their ends upon the sides of a hollow pagoda[1] drum in an overlapping manner, and curved to fit it. The field is a complex one, with an external and six internal poles, and is very powerful magnetically. The coils are wound in two parallel lengths about each, and are connected together as to work as three machines, and feed three pairs of brushes; which may again be worked, either in series or in parallel, or may be used to feed three separate circuits.

Collectors.

In a well-arranged dynamo of the first class, the sections of the collector are insulated by cement, or by mica, from the axis, and are also insulated from each other by mica, or by air, and great at that part of the collector which touches the positive brush, the potential is equal to that of the circle formed by collecting cylinder, in both directions, becoming a maximum at the opposite side where the positive brush is. This can be verified by connecting one terminal of a voltmeter to the axis of the drum, and touching the rotating collector at different points with the other terminal, a small metallic brush resting attached by a wire to the other terminal of the voltmeter. If the indications thus obtained are plotted out round a circle corresponding to the circumference of the collector, the values give a curve like that shown in Fig. 22, which is obtained from observations taken upon a Gramme machine.

If this curve be then, taking the negative brush as the lowest point of the circle, the potential rises perfectly regularly to a maximum at the positive brush. The same values are also plotted rectangularly in the curve shown in Fig. 23, in which the ratio of distance shown very nearly that the rise of potential is not equal between each pair of bars, otherwise the curve would consist merely of two oblique straight lines, sloping right and left from the central point. It is the existence of these small little differences of potential between the collector bars which causes the brush on its right and left respectively. The greatest difference of potential occurs where the curve is steepest, at a position nearly 90° from the brushes, in fact, at that part of the circumference of the collector which is midway between the brushes, or at the end of the insulation which separates the two field positive brushes. When the field positive brushes. When the field positive brushes. When the

DYNAMO-ELECTRIC MACHINERY.

ON Monday night Prof. Silvanus P. Thompson delivered the second of the Cantor lectures for the session 1882-3 on Dynamo Electric Machinery in the hall of the Society of Arts, Adelphi. Dealing with the dynamo in practice, he said that the first point to consider was the forms of combination used for producing either constant strength in the current or constant difference of potential. Next, as to the principles of construction, the action of the machine must be entirely automatic, so that the removal of lamps from one part of the circuit should not in the least affect any other part. Turning to various points in which theory had been put into practice in different developments of dynamo-electric machines, he commenced on the forms of the magnets, the pole-pieces, and the methods of construction of same. He then pointed out the essential differences between the continuous current machine and an alternate current machine, and the peculiar arrangements of the more interesting types, such as those of Zilliwell, Brush, and Gülcher, and the distribution of potentiality on the commutators of dynamos he had particularly examined, and he referred to the theory of the alternate current machine, and to the best form for the construction of armatures and field magnets. He might observe that science had now advanced so far that it could point out how machines could be constructed with a full knowledge of what their actual performances would be. The subject of the succeeding lectures is the dynamo as a motor.

DYNAMO-ELECTRIC MACHINERY.—VI.*

By Prof. S. P. Thompson, B.A., D.Sc.

(*Continued from p. 491.*)

The Brush Dynamo.

BEFORE passing on to the dynamos of the second class, in which currents are branched off from main non-continuous or non-annulated armature machine, the Brush dynamo. In this machine the ring is form, not simply the overwound with coils, but having projecting teeth between the coils like the Pacinotti gramme wheel. Though it thus resembles Pacinotti's ring, it differs more from the Pacinotti machine than the Pacinotti machine differs from the Siemens machine. The coils are connected in pairs, each to that diametrically opposite, and the junctions are connected to the segments of the commutator, which, in the case of a ring of eight coils, there are four distinct segments, future side by side upon the axis—one for each pair of coils. The brushes are arranged so as to touch at the same time the commutators of two pairs of coils, the diameter of two adjacent pairs; the adjacent commutators being always connected to two pairs of coils that lie at right angles to one another in the ring. The arrangement is best studied graphically from the diagram given in Fig. 25. In this figure, the eight coils are numbered as four pairs, and each pair has its own commutator, the two halves of the outer end of the wire of each coil, the four ends of the two coils being united across to each other, and to the four segments of the commutator. Each pair of coils, as it passes through the position of least action, is then in the plane at right angles to the direction of the lines of force in the field, and when the number of lines of force passing through it is a maximum, and the rate of change of these lines of force a minimum, the current in the coils is zero. This is occasionally by causing the two halves of the commutator to be separated from one another by a greater breadth of the circumference at each side. In the figure it will be seen that the coils marked 1, 1, are "cut out." Neither of the two halves of the commutator touches the brushes. In this position, therefore, the coils 2, 2, at right angles to 1, 1, are in the position of greatest action, and the current powerfully induced in them flows round the coil marked A, which is, therefore, the negative branch into that marked A'. This branch is connected across

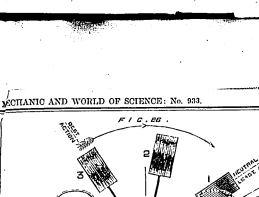


DIAGRAM OF THE BRUSH DYNAMO.

to the brush marked B, where the current re-enters the armature. Now, the coils 2, 2, have just left the position of best action, and the coils, 1, 1, are beginning to approach that position. Through both these pairs of coils, therefore, there will be a partial current flowing as yet. Accordingly it is arranged that the commutator, on passing into this phase, is going through a gap in the brush, and, while the coil connecting at the brush B, whereto the current flows round the coils of the field-magnets to earth and then round the external circuit, and back to the brush A. (In some machines it is arranged that the current shall go round the field-magnets after having brush A, and before reaching brush B.) Now, in this position of the machine, in succession, though not theoretically described as causing its coils, as they rotate, to cut the field-magnets and the external circuit alternately. The rotation of the armature will then bring coil 2, 2, into the position of least action, when they will be cut out, and the same action is repeated again. Only a slight change in the order of operations is needed, following table summarises the successive order of connections during a half-revolution:—

First position. (Coils 1 cut out.)

$$A - 3 - A; B \lessgtr \frac{}{} B; \text{Field-magnets}$$

$$\text{— External circuit —} A.$$

Second position. (Coils 2 cut out.)

$$A \lessgtr \frac{}{} A; B - 4 - B; \text{Field-magnets}$$

$$\text{— External circuit —} A.$$

Third position. (Coils 3 cut out.)

$$A - 1 - A; B \lessgtr \frac{}{} B; \text{Field-magnets}$$

$$\text{— External circuit —} A.$$

Fourth position. (Coils 4 cut out.)

$$A \lessgtr \frac{}{} A; B - 2 - B; \text{Field-magnets}$$

$$\text{— External circuit —} A.$$

From this it will be seen that whichever pair of coils is in the position of best action, is delivering its current into the circuit; whilst the two pairs of coils into the positions of least action positions are always joined in parallel, the same pair of brushes touching the respective commutators of both.

One consequence of the peculiar arrangement thus adopted is, that measuring the potentials round one of the commutators with a voltameter gives a wholly different result from that obtained with other machines. For example, when the circumference on either side of the positive brush, there is no sensible difference of potential. Then these coils remain in which the potential appears to fall off; but the falling off is only partly due to the shorter time during which the adjustable coils remain in contact with the volameter and the fixed positive brush as both in contact with the same part of the commutator. There is a certain short region in which the voltmeter gives no indication corresponding to the cut out position; and upon on each side of the negative brush, there is a region where the potential is the same as that of the negative brush. Fig. 27 is a diagram of the results that are taken at one commutator, the main—brush being, as before, supposed to be on the usual position, in contact with both the commutator and the adjacent one.

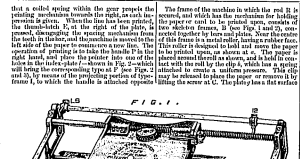
From the foregoing considerations it will be clear that the four pairs of coils of the Brush machine really constitute four separate machines, each delivering alternate currents to a commutator, which commutator is in its turn split into a number of current-bits in the brushes; and that these independent currents are subsequently united in parallel arc, the device of bringing pairs of brushes into contact with the commutators of two pairs of coils. Further, that these joined machines are then connected in series, by bringing a connection round from brush A to brush B.

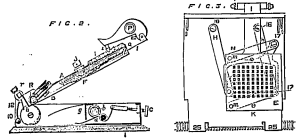
The following experiment illustrates the independence of the four pairs of coils in the Brush dynamo.* The usual commutators of a small

Brush dynamos were removed and replaced by eight insulated segments, two for each coil, and the brass collars, to each of which was united one end of one of the four pairs of coils. And upon these rings pressed eight separate brushes, and the eight

that a coiled spring within the gear propels the printing mechanism towards the right, as each impressing stroke is made, the line has been printed, the thumb-stud, A, at the right of the plate, is pressed, disengaging the pinion-wheel, and allowing the teeth in the bar, and the machine is moved to the left side of the paper to commence a new line. The operator of printing is to take the handle P in his right hand, and place the pointer into one of the holes in the index-plate (shown in Fig. 2—which will bring the corresponding type at P (see Figs. 2 and 3), under the pointer. The printing-action of type-frame, I, to which the handle is affected opposite

The frame of the machine in which the rod R is secured, and which has the mechanism for holding the paper or card to be printed upon, consists of two skeleton frames, B (see Figs. 1 and 2), connected by the bars, C, supported by the feet, D. Portions of this frame is a metal-rolled, hardened rubber face. This roller is designed to hold and move the paper to be printed upon, as shown at e. The paper is placed around the roll as shown, and is held in contact with the roll by the slip, d, which has a spring attached to create a uniform pressure. This slip can be released by the two levers, f, and g, when lifting the screw at G. The platen has a flat surface





to the post J, and over a small opening in the bottom plate B; so that a slight pressure carries down the whole plate A, swinging on hinges O, O, and the post J presses the type to be used through the opening, and on to the paper, which rests on our flat-topped bar p, while all the motion is given to the type-bearing plate A, and the bottom plate B is at the different characters on each. The types are continually changing their position on the post, and the ink is continually distributed and re-applied. Two spring-arms, Q, raise the plate A, and type-frame with it, from the paper until the next stroke or impress is removed.

Form F (see Fig. 3) containing the type and other characters for which there are 72 in all, is made of brass material, especially prepared for that purpose.

This form is attached by screws to the frame-plate. Each individual type and character in the form to be printed is brought under the type-bar, and in front of the paper, by the index-plate by a very ingenious piece of mechanism. The printing of the paper is effected to regulate the pressure upon the types to the greatest nicety, the plate A going down in a step.

The mechanism above mentioned may be understood by an inspection of Fig. 3, where the under side of the plate A is shown. The letter F is pivoted to the main plate at one or links at so, so. These links are also pivoted at 17, 17, to the frame K, having a curved slot to admit the post J. This frame is pivoted to one end of the links H H, while the other ends are pivoted to the plate A at 16 16.

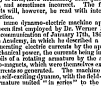
From this it will be seen that a pantographic motion is produced when the plate A is moved vertically upon the frame K, allowing it to move freely in all directions. When a word has been completed, a space is made by depressing the key S with the little finger without letting go of the handle.

DYNAMO-ELECTRIC MACHINERY.—II.*

By Prof. S. P. Thompson, B.Sc., D.Sc.

THE brief records of the lectures recently delivered by Prof. S. P. Thompson, before the Society of Arts, have successfully been quite inadequate, and sometimes incorrect. The following extracts will, however, be read with interest and advantage.

The same dynamo-electric machine appears to have been independently made by Mr. Varley, and in his recent lecture of January 12th, 1867, to the Berlin Academy, in which he described a machine for generating electric currents by the application of mechanical power, the currents being induced in the coils of a winding armature by the action of electro-magnets, which were themselves excited by the same currents. Mr. Varley's machine was, in fact, a self-regulating dynamo, with the field-magnets and armature united "in series" to the external circuit, or what we now call a "series-dynamo," a diagrammatic representation of which is given in Fig. 1. But the term dynamo-electric machine,



THE SERIES DYNAMO.

then introduced into electric technology, has not remained then restricted to its successful meaning. It was extended to machines of kindred nature, in which, though self-excited, only a portion of the current was utilised externally, the remainder was applied to excite the field-magnets (see Fig. 2).

THE SHUNT DYNAMO.

This principle of working (now known as that of the "shunt-dynamo"), first introduced by Wheatstone, is but a variation of the former arrangement in detail, and no violence is done to the original meaning if we apply it to both cases. In fact, the name was evidently so being convenient in practice for distinguishing between machines in which the whole current was utilised, and those which either used magnets or self-excited machines in which the current was divided between the external circuit and the magnetic field.

Since the great development of electric lighting has been found necessary to use generating machines in certain combinations, in order to obtain the best results. Thus, in machines where systems of electric light involve alternating currents, produced in machines which cannot excite their own magnets with a continuous magnetisation; and there are other systems where continuous currents are employed, in which also practice has shown that the currents are better regulated when they are not employed to excite the magnets which by currents derived from an outside source. Then, a third class of dynamo-electric machine, the "separately-excited dynamo" (Fig. 3), which was indeed earlier than either of the preceding, having been brought out by Wilde in 1864. A

combination of bones. Continuing the subject of compound eyes for a short space, he would make two experiments with a solar microscope. To some present they might be familiar, but they would be new to most of them. In the sunshine saw before the microscope a piece of glass, on which were illuminated there some the picture in the sunshine, and body, the lenses which produced the vastly magnified image of that picture. In one experiment the solar microscope would enable them to see how the insects preserved by the infiltration in the pounds of chloride of ammonium, which was used for the purpose. The action of hot waters carried on. Numerous experiments were perfectly successful, and as the chloride began to crystallize in the course of the experiment, and in the latter the broken trees or trees were dropping their fronds into the water as they grew too heavy to stick to the magnetic pole, and again when, as required by the electric current, they floated away in misty clouds of green. Another experiment was with platinum wire as branches of a new stem, there was loud clapping of hands. The whole business, as the lecturer did not forget to remind his young friends, was conducted in the darkened theatre, and was exercised with a certain amount of such as photographers used. His own apparatus, he said, would interest them, for it was the first time it had been publicly used. The human eye optically acted on the principle of the lens, and was illustrated with the aid of a lens. The position of the lens was pointed out that of the screen on which the image to be formed, and due reference was made to inversion of the image. The picture which Murray was allowed to exhibited was a very fine one of the Lion Gate of Mycenæ, and was thrown upon the white sheet or screen, and next forgotten to point out in that since the white picture Mr. Cottrell's pallid face was lighted with an Ethiopian hue. To occupy minutes while the image was further developed Mr. Murray showed a few slides which were of the photographer's friend Dr. Tyndall and his family, and the audience recognized the features in a manner that showed a sufficiently accurate section of the eye, as the most interesting subject of all. He proceeded to give, in the most popular style, the theory of vision, and the action of the lens, and of the various living acres, the retina. By way of illustrating the inverted action of the organ of vision was thrown shown in a model. This done, those present were necessary to distinct vision. A large bird-cat was filled with water to represent an artificial human eye, with tracing-paper behind for a retina, and a lens in front. The lens was in a movable pasteboard tube, and the lecturer, by moving this in the animated water-door, the hands before the eyes of the audience. A luminous explanation was given of both short and long sight, and of the means by which the errors of vision thus caused might be rectified. The lecturer, in illustration of the conditions of short-sightedness, threw the water-lens nearer to the retina, and with a more thick was all that was to be seen; and in that of long-sightedness, by making paper away the image was brought behind it. The same purpose was answered by introducing a lens of shortness, which reduced the image to be fairly sharp. By drawing the water-lens too far from the retina there was again a blurred image. The lens falling within its rod. The introduction of a lens of greater length than the eye required threw the image before it, thus remedying the defect. The luminous rays surrounding the image were seen on the screen was due, he said, to the divergence of the rays which was caused by spectators of that kind. He was specially struck by one of the produced exceedingly sharp images of the coloured rings, and the illustration of peculiarities of vision among persons was discovered by Dr. Tyndall the day before. The paper was pierced with a number of holes, each a luminous circle was seen.

Professor Tyndall's fourth lecture dealt with sound, as it is produced apparatus, was capable of conveying impressions made upon it by the human ear, and of re-uttering them the sensation of light. There was a phonograph at the back of the stage, and the lecturer began by explaining how sound when the ear was produced. He showed that the vocal and nasture pulsations had been applied in one of Edison's vocal tones into socket to render the image visible. Standing general view upon a new and interesting subject, as the lecturer said, he could not do better than refer his audience to the pages of Dr. Rowton, by which he discussed the constitution of light. Newton made a hollow-shutter, and allowed a sunbeam to fall and thereby itself as a round disc of light. Dr. Young, by the use of two pinholes, made two discs, which overlapped, and by refraction, but by the introduction of a third piece he found that the refracted image would be white. What in really saw, as a repetition of the experiment showed, was the prismatic spectrum with its seven colours, into which white light had, in fact, been analysed. The colours they saw on the screen were red, orange, yellow, green, blue, indigo, and violet. Then a prism was put in the pinhole, and they were commonly styled prismatic. Newton found that when the mixture was properly made the original white light appeared. They would follow the great philosopher in the synthesis, as he had in the analysis; and to make the experiment successful, the lecturer allowed the light to fall from a pinhole on a prism, and then on a lens, and without going into the question of the colours by means of a cylindrical lens, which, as he graphically expressed the effect, screwed them together, producing a rectangle of perfectly white light. Having proved the matter to their entire satisfaction, he built up from the coloured spectrum the white light. Besides of the electric light, which produced it. Besides of the common glass prism for Thallium, a slide which far more brilliant display, leading up to an examination of how the colours of mineral objects—foliage, flowers, grass, and dyes—were produced. When the spectrum fell upon a red-stained screen, they saw that it was the only colour given back by the element. What became of the other coloured rays? They were absorbed by the screen, and the electric current, and had been produced, as light, by the flannel. The red light plunged into the flannel, struck on the fibres, was reflected back to the eye. The fibres of the flannel were transparent to the red, and reflected red, while the green and blue were opaque to all the other colours of the spectrum, and so absorbed the rays. A coloured body was chosen and looked to the eye the particular light in which it was transparent. Thus, a green body looked in the light which was transparent to it, and appeared black when the light fell upon them. Dr. Tyndall then produced the effect of green as the result of red light, to which he appeared in succession red, yellow, green, blue, and violet. What, he asked, must be the result? There was neither green nor red, but simply white light. The lecturer then threw the green and blue through a prism, and the resulting white. How, then, must these appear when the green and blue were thrown on the screen? The green and blue showed black, red, on the contrary, being redder than green, and the remainder of the rays glow blackness at once vanished, being replaced by the true colour.

THE EAR IN HEALTH AND DISEASE.

DR. R. J. BLAIR CUNNINGHAME, Superintendent of Statistics in the Local Government Department, delivered a lecture on "The Ear in Health and Disease," before the Edinburgh Health Society on Saturday last. Diseases of the ear were responsible for a large number of deaths annually. Their consequences were often very serious. Many cases of deafness, and not a few of blindness, were due to aural affections, to success in business, his intellectual powers, and even his moral character might be seriously damaged by the disease. The researches of the last few years had thrown much light on the causes of deafness, but it was not so; and inattention to the simplest rules was strongly impressed upon his hearers that pricking of the ear with a pin, or anything else, often caused great injury being done to the drumhead, which caused deafness. There were two kinds of deafness—nervous and mechanical—the former being caused by the brain and the ear. Forgiveness or hardening of the wax in the ear was accompanied by noises in the head, pain, and deafness, an easy remedy was to be found in the use of soft soap and a little tepid water. If they found the wax hardening, a little clean water, or with a little soda in it, might be put into the ear, and then any foreign bodies got into the ear, the simplest remedy was to syringe it out. Whatever was put into the ear, except the finger, should be of the same temperature as the body. If the wax was not affected, the syringe must again be used. The best way of treating deafness in the nervous form was to fill the ear with warm water from a spoon, or by means of a syringe, but plugging must be carefully avoided. To avoid injury to the ear when bathing, and especially when diving, the best way was to put a small bit of wadding in the ear. Alluding to the drumhead being often ruptured by a blow, the lecturer pointed out that the opening of the mouth, as was done by persons discharging large guns, allowed the air to reach the ear through the air-valve in the throat, and thus prevented injury. Another way was to extend the tube of the ear, and the effect of the wave-sound was then equalised and prevented injury. Speaking of the effect of blows on the side of the head and ear, he adopted pounds and shillings as the usual fine that fell here as punishment. If punishment was actually necessary, he would suggest that the fine be in the form of a blow from the prisoner's own hand. The blow was to be delivered on the part in question, and the striking power was calculated by the lecturer. Cunningham, speaking of running cars, said that these cars were already fitted for the use, on account of the close contact with the brain, was especially dangerous of inflammation as early as it. One cause of this disease was the practice of "boxing the ears," which he pointed out how extremely careful it was to give careful attention to the ear, especially if the slightest symptom of pain in the head or ear. Another result of this inflammed condition was the perforation of the membrane. This perforation was as a consequence of running ears; so by attending to the ear in time, they might save it. He also referred to the connection between the ear and the eye. Cases had come under his notice of the syringe to perforate the membrane. The most common cause of deafness was the result of cold, perhaps neglected for a time, but which was the source of great suffering to the thoughtful ought to be avoided. In conclusion, the lecturer said that a person who was deaf in one ear of the ears, and neither of the ears could be used, and there was no reason why they should not live a long and happy life. Cunningham moved a vote of thanks to the lecturer, which was seconded by Mr. Cunningham, and supported in a few remarks by the chairman, Dr. Littlejohn, who expressed the German method of training them by listening by speech to make them useful members of society.

DYNAMO-ELECTRIC MACHINERY.—No. 2.

By PROF. S. P. THOMPSON, B.A., D.Sc.

The Relation of Speed to Power.

THEORY shows that, if the intensity of the magnetic field and the resistance of the circuit remain constant, the electromotive force should be proportional to the speed of the armature. Numerous experiments, by me, and by other workers, have shown that this is the case. Hence, in a machine in which the strength of the field and the resistance of the circuit remain constant, the speed for magnets and separately-excited machines. It is not, however, quite easy to maintain the resistance of the circuit be increased proportionally to the speed, because the current also calls itself exerts on the magnetic field, and alters the strength of the field. In fact, as the current in the coils of the machine is itself, it is positive to the "distance of commutation." If altered coil, the effective number of lines of force is reduced. So that, with a constant resistance in circuit, the electromotive force, and consequently the current, are slightly less at high speed than they would be at low speed. It is usual to use to cancel this effect by the use of extra field-coils, whose motive force gives a number proportional to the

* Extracted from the Course Lectures, delivered before the Society of Arts.

electric work of the machine, it follows that, for "independently excited" machines, the electric work done in generating is nearly proportional to the square of the speed, and the work drawn from the steam-engine by the machine is nearly proportional to the square of the speed.

Hence, in such machines, whether "series" or "shunt" coil machines, the efficiency is nearly somehow constant. If the iron of the field-magnets is not saturated, the efficiency is nearly constant, on account of current consequent on increase of speed produces a nearly proportional increase in the strength of the magnetic field, this increase will not be proportional, because the iron cores will be in proportion of saturation, and so cause a loss of velocity, which again will cause the current to increase in the proportion. But since the magnetisation of the iron is, even when far from saturation-point, not exactly proportional to the magnetising force, but somethings less, it is in practice found that the increase of the electromotive force is proportional to the fourth power of the speed, and even less proportional to the third power of the speed. This is generally the case with Siemens machines.

As mechanical considerations forbid too high a velocity in the moving parts, it is usual, in Siemens machines, to make the armature of the shape which it is safe to run any speed, the speed of the armature of work will be done in the armature, and the remainder will be done in the field-magnets, which are therefore made as large as possible.

Field-Magnets.

The coils of the field-magnets of a dynamo can not be considered of no resistance. In a Siemens machine, always make some of the energy of the current to be wasted in the coils, for although that it cannot be economised to one electro-magnets is somewhat unfavourable to economy, yet it is practically safe to be neglected, even for all Siemens machines of moderate dimensions. Hence, in a well-formed electro-magnets, the weight of copper in the coils should be about equal to the weight of the iron in the cores, and the weight of the iron in the yokes and pole-pieces should be about equal to the weight of the iron in the cores. But if we do not get our magnetism for nothing, and that is one very common error. Let us take a current upon the electro-magnets, economy dictates that we should so construct that the number of convolutions may cost us as little as possible. To magnetise the iron to a given degree of saturation, we require a certain number of ampère-turns. The product of the current into the number of turns in the coil, perhaps neglected for a time, but which was the source of great suffering to the thoughtful ought to be avoided. In conclusion, the lecturer said that a person who was deaf in one of the ears, and neither of the ears could be used, and there was no reason why they should not live a long and happy life. Cunningham moved a vote of thanks to the lecturer, which was seconded by Mr. Cunningham, and supported in a few remarks by the chairman, Dr. Littlejohn, who expressed the German method of training them by listening by speech to make them useful members of society.

Field-Magnet Coils.

If, in order to be of the greatest possible service, the coils of the field-magnets should be so constructed that the whole of the copper be evenly and distributed uniformly along its length, not put round about the yoke. The power of a magnet is proportional to the square of the magnetic flux through the cross-section of the magnet before the pole-pieces, and to the square of the number of turns of wire round the magnet. Accordingly, the magnetisation of the magnet is greatest at its middle, and least at the ends. Hence the following practical rule:—

Wind the field-magnets as much iron as possible. The greatest number of turns should be at the middle, and the least at the ends. If this rule is not observed, it is the case of Siemens machines which are constructed with the armature in the middle of the field-magnets, and the coils are wound equally all along the magnets. In such machines the

(*Continued from p. 447.*)

The Dynamo in Practice.

IT was pointed out, at the conclusion of the former lecture, that none of the four fundamental methods of exciting the field-magnetism of a dynamo was perfect in theory, since none could enable a machine either to generate a constant electromotive force, or a constant current, of any form, whatever the resistance of the external circuit for the time being. Now, as the first function of a dynamo in practice is to work with efficiency and regularity a system of lamps, and as these lamps are always in practice arranged either in series or in parallel, it is clear that in the former case a constant current, and in the latter a constant electromotive force, is required.

Combination Methods.

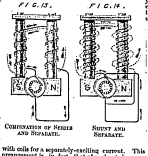
As this matter promises to be of utmost importance in the future practical considering dynamos, a summary of the principal methods may be worth tabulating.

(1.) *Series and Separate (for Constant Current), Dynamo.*—This method, illustrated in Fig. 15, can be applied to any ordinary dynamo, provided the coils are such that a separate current from an independent source can be passed through a part of them, so that these shall act initial magnetic field, independent of the main current current of the dynamo. When the machine is running, the electromotive force generated will depend partly on this independent excitement, partly on the current's own excitement of the field-magnets. If the machine be run at such a speed that the quotient of the part of the electromotive force due to the self-excitement, divided by the strength of the current, is numerically equal to the external resistance, then the whole electromotive force in the circuit will be constant.

* Extracted from the Cantor Lectures, delivered before the Society of Arts.

However, the external resistances are varied. M. Deprez has further shown that this velocity can be found by direct experiment, and that, when the required velocity has once been determined, the machine can be adjusted to give any desired electromotive force, by varying the strength of the constantly-exciting current to the desired degree.

(2.) *Shunt and Separate (for Constant Current), Dynamo.*—When cases arise, as for a set of arc lamps in series, it is desired to maintain a constant current in the circuit at one constant strength, the following arrangement may be made, and is described in Fig. 16, by combining a shunt-winding



COMPOUNDING OF SERIES AND SEPARATE.

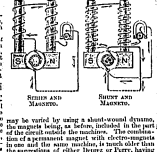
SHUNT AND SEPARATE.

with coils for a separately-exciting current. This arrangement is, in fact, that of a shunt-dynamo, with an initial magnetic field independent of the strength of the current in the circuit.

Seeing that the only object in providing the coils for separate excitement is to secure an initial and independent magnetic field, it is clear that either means may be employed to bring about a similar result.

(3.) *Series and Magneto (Constant E.M.F.).*—The initial electromotive force in the circuit, required by Deprez's theory, need not necessarily consist in the making an initial magnetic field of independent origin. It is true that the addition of a permanent magnet, to give an initial portion of magnetism to the pole-pieces of the field-magnets, would meet the case to a certain extent; but Deprez has shown that it is better to secure the solution of introducing into the circuit of a series dynamo a separate magneto machine, also driven at a uniform speed, such that it produces in the circuit a constant electromotive force equal to that which it is desired should exist between the leading and return mains (supp. 529, Vol. XXXV).

This arrangement, which is shown in Fig. 15,



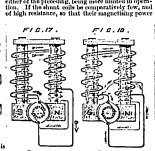
SERIES AND MAGNETO.

SHUNT AND MAGNETO.

may be varied by using a shunt-wound dynamo, the magneto being, as before, included in the path of the circuit outside the machine. The combination of a permanent magnet with both series and shunt windings, as described by other inventors, is the suggestion of either Deprez or Perry, having been described by Hjorth in 1854.

(4.) *Shunt and Separate (Constant Current), Perry.*—Perry's arrangement for constant current is given in Figs. 16, and consists in some way combining a shunt dynamo with a magneto machine of sufficient power to maintain the field-magnets of the machine together either in the armature, or in the magneto-shunt coils of the machine. As before, a certain critical speed must be found from experiment and calculation.

(5.) *Series and Shunt.*—A dynamo having its coils wound, as in Fig. 17, so that the field-magnets are excited partly by the main current, partly by a current derived from it by a shunt of higher resistance, will have its dynamic properties greatly modified by having been used in dynamos for some years past. The arrangement is used as perfect as either of the preceding, being more limited in operation. If the shunt coils be comparatively few, and of high resistance, so that their magnetising power



SERIES AND SHUNT.

SERIES AND LONG-SHUNT.

is small, the machine will give approximately a uniform electromotive force; whereas, if the shunt be relatively a powerful magnetiser, as compared with the few coils of the main circuit, the machine will be better adapted for giving a constant current; but, as before, each case will correspond to a certain critical speed, depending on the arrangements of the machine.

(6.) *Series and Long Shunt.*—I propose to give this name to a combination closely resembling the preceding, which has not yet, so far as I am aware, been actually tried. If, as in Fig. 18, the magnets are excited partly by a few coils in series with those of the armature, and partly by a shunt current of high resistance, from the combination should be found, Edison's dynamo, indeed, are still remarkable in this feature; the pole-pieces and the yoke connecting the iron cores of the coils are made bluntly heavy. This is not more noticeable in the giant dynamos, than in the smaller machines of the reduced installations for sixty and for fifteen lights.

The principle of shaping the outpoint so that their external form approximates to that of the magnetic curves of the lines of force, is to some extent carried out in such widely differing types of machine as the Siemens with "Zenith" magnet, the Jürgensen dynamo, and Thomson's "mouse-trap" machine. In the last-named machine I noticed several curious contrasts. In the Jürgensen the field-magnets have heavy pole-pieces; in the Thomson there are none; and in the Thomson machine the iron core is thicker at the middle than at the ends. In both there are auxiliary internal electro-magnets, fixed within the rotating armature, to help to excite and augment the intensity of the field. In the Thomson machine these are disposed as more thickly at the middle of the field-magnets; in the Jürgensen, the coils are crowded up around the poles. If we may judge from a report on this machine by Professors Ayrton and Perry, the armature is not satisfactory in practice, as there are more core coils than suffice to magnetise the magnets. It is possible that the mistake is the other way in the Jürgensen coils, but in having them in the wrong place.

Another suggestion, which was indicated from theoretical considerations, was that of insulating the pole-pieces, so as to prevent the production in them of wasteful Foucault currents. Here I find that but one machine has been designed in which this precaution has been taken, viz., the Mordey dynamo of Bro. Hopkinson and Muirhead, the field-magnetsof which are made up of laminæ of iron, cut into a solid iron backing.

Another matter in which, up to the present time at least, there is nothing but empirical practice to guide us, is the form to be given to pole-pieces, in order to produce the best effects. It is clear that the object of the designer in practice as to suggest the thought that little importance has been attached to the matter. Yet upon the form and extent given to the pole-pieces depend considerations of no low importance than the reduction of idle wire in the armature, the reduction of sparking at the commutator, and the production of the best electromotive force in the armature. If the pole-pieces are badly shaped for their work, or approach too near to the round the armature, they may completely pervert the approximate uniformity of the field, and may cause the rotated portion of the field to be of much weaker intensity than the two lateral regions of the field, because of the pole-pieces. In such a case, the armature coils, actually moving in a double field, and it is even possible that, in consequence, the direction of the currents induced in the individual coils may be reversed four or six times on their passage rotation. In such a case the distribution of potential round the separate bars of the commutator will be abnormal, as we shall see later on.

(To be continued.)

amount of iron employed in the field-magnets would be quite insufficient if it were not of high quality. As it is, I am of opinion, the mass of it (especially in the polar parts) might, with advantage, be increased; in some of the early machines of Wild, Ferranti, Siemens's well-known dynamos, long field-magnets with large cores had been found. Edison's dynamo, indeed, are still remarkable in this feature; the pole-pieces and the yoke connecting the iron cores of the coils are made bluntly heavy. This is not more noticeable in the giant dynamos, than in the smaller machines of the reduced installations for sixty and for fifteen lights.

The principle of shaping the outpoint so that their external form approximates to that of the magnetic curves of the lines of force, is to some extent carried out in such widely differing types of machine as the Siemens with "Zenith" magnet, the Jürgensen dynamo, and Thomson's "mouse-trap" machine. In both there are auxiliary internal electro-magnets, fixed within the rotating armature, to help to excite and augment the intensity of the field. In the Thomson machine these are disposed as more thickly at the middle of the field-magnets; in the Jürgensen, the coils are crowded up around the poles. If we may judge from a report on this machine by Professors Ayrton and Perry, the armature is not satisfactory in practice, as there are more core coils than suffice to magnetise the magnets. It is possible that the mistake is the other way in the Jürgensen coils, but in having them in the wrong place.

Another suggestion, which was indicated from theoretical considerations, was that of insulating the pole-pieces, so as to prevent the production in them of wasteful Foucault currents. Here I find that but one machine has been designed in which this precaution has been taken, viz., the Mordey dynamo of Bro. Hopkinson and Muirhead, the field-magnetsof which are made up of laminæ of iron, cut into a solid iron backing.

Another matter in which, up to the present time at least, there is nothing but empirical practice to guide us, is the form to be given to pole-pieces, in order to produce the best effects. It is clear that the object of the designer in practice as to suggest the thought that little importance has been attached to the matter. Yet upon the form and extent given to the pole-pieces depend considerations of no low importance than the reduction of idle wire in the armature, the reduction of sparking at the commutator, and the production of the best electromotive force in the armature. If the pole-pieces are badly shaped for their work, or approach too near to the round the armature, they may completely pervert the approximate uniformity of the field, and may cause the rotated portion of the field to be of much weaker intensity than the two lateral regions of the field, because of the pole-pieces. In such a case, the armature coils, actually moving in a double field, and it is even possible that, in consequence, the direction of the currents induced in the individual coils may be reversed four or six times on their passage rotation. In such a case the distribution of potential round the separate bars of the commutator will be abnormal, as we shall see later on.

(To be continued.)

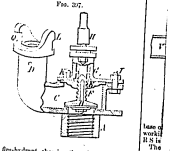
* Since the above was written, an account of a similar combination by the 5th mentioned above has appeared under the name of Crompton's Compound Dynamo. Mr. H. Crompton, jun., has also described to me privately a somewhat similar arrangement for charging accumulators with a constant electromotive force.

In Siemens's machine the two classes of machine. In the first, we have usually two pole-pieces on opposite sides of a rotating armature. In the second, a couple of series of coils, or of independent magneto-coils, are used, the coils which rotate being at equal distances between two such courses of poles.

Confining ourselves, at first, to the first-class of machines, we find that in practice, their magnets differ widely in construction and design. In very few of the existing patterns is there much trouble taken to secure steady magnets, by using a good, long, heavy, and solid, of with very heavy pole-pieces. Even in the powerful Gramme dynamos, last report tried an unnecessary amount of wire had been wound upon the field-magnets; and I find that the usual reply is that with less wire the machine does not work so well. If, however, it is found necessary to wind so as many coils upon the magnets as to bring these practically to saturation, it is clear that either the iron is insufficient in quantity, or it is deficient in quality. In the Hefner machines, where cast-iron field-magnets are employed, the smaller magnetic susceptibility of this metal is made up for by employing a good weight of it. In Siemens's smaller dynamos, the

by so doing the aperture over the seating T is opened, and the water allowed to run during the time that this diaphragm remains off the seating, or falls which causes the water to flow in a small fo ks passage at A, which allows the water to pass freely from between the bottom diaphragm C, or vice versa; that is to say, when the top diaphragm is depressed, and the lower diaphragm down, the water will be forced back through the small aperture A. Sometimes the falling piece or pallcen is worked in conjunction with the diaphragm, a modification of which is shown at C in L and G (Figs. 206, 207, &c.). Sometimes the outlet valve is formed on the diaphragm, and a piston made to actuate the diaphragm, whilst at other times the diaphragm is made to actuate the falling plug, &c. At Fig. 207 is a section of

FIG. 207.



the fire-by-draut, showing the valve to be of the beam-valve kind (as in the Rotherham cock, the difference being the plate B, and round the spindle a stuffing-box with glands, G holds the face of the diaphragm and features to the valve-

lat. Because the wires of the armature, second heated, conduct less freely; hence loss of curr 2nd. Because the armature itself is not exp of such intense magnetisation when hot as w cold (a red-hot mass of iron is hardly affecte the magnet); hence another loss of current.

Heating of the armature consequent on the wir impaired, even if not actually ruined, if temperature rises to a very moderate limit.

For these reasons it is important to keep temperature of the armature as low as possi The first step and step in this direction taken by Dr. Pacinotti, of Florence, in 1 who constructed an armature of soft iron, in shape of a ring, around which were coiled successive sections, before it was insulated coa wire, the ends of which were joined up t divided ring commutator. The ring armatur soft iron, with its covering of wire, was supp on a central axle, and rotated before the pole a magnet, either permanent or electro, part of the revolution in such a way that whole further from, or nearer to, the poles of magnet; and although its magnetism is c stantly changing, yet the change is not abr but gradual and continuous: as will be explai in the following paragraph.

Pacinotti's Ring Armature.

[17. The description and illustration of machine is to be found in the *Nuovo Cimento* the year 1864, under the heading of "Descrizione d'una Piccola Macchina Elettro-M netica." The machine itself, as described, be used either as a motor, or as a generato electricity; and its adaptability to either p pose was specially dwelt upon by Dr. A. F notti, in his communication; but it is only as the aspect of a generator that we shall str consider it here.

Alternate-current Dynamos.

Electricity for the most important of the dynamos of this second class are those of Siemens and Wheatstone, *alternate-current machines*. The type of alternate-current machine first invented by Wilde, in 1867. The field-magnets are arranged as those of fixed coils, with iron cores, arranged so that their free poles are opposite to one another, with the armature between, sufficiently wide to embrace the armature. The poles taken in order round each groove in the armature are north and south polarity, and opposite north pole of one crown faces a south pole of the other crown. The same rules will apply to the magnets of the alternate-current machines of Wilde and Siemens as to those of the Gramme machine, and, with certain modifications, to Dr. Siemens's and Ladd's machines. The armature, as in the Gramme, is a ring of soft iron, bearing at least two coils of wire, but usually a number of coils, whose ends are parallel to the plane of rotation. The machine itself, as described, may be used either as a motor, or as a generator of electricity; and its adaptability to either purpose was specially dwelt upon by Dr. A. F. Pacinotti, in his communication; but it is only as the aspect of a generator that we shall at present consider it here.

THE DYNAMO: HOW MADE AND HOW USED.—VIII.*

By Selsey R. Bottone.

The Patterns.

§ 18. IN the dynamo we are about to construct, all three separate sizes for patterns are absolutely necessary—viz., one for the armature, one for the legs of the field magnets, and one for the standard which supports the flywheel. There is no necessity for the amateur to put himself to the trouble of cutting out a pattern for the flywheel, since such wheels with handles already fixed can be had for two or three shillings. In constructing the wooden patterns, from which the iron castings are afterwards to be procured, the amateur should remember to choose dry, well seasoned wood, free from knots. Red pine, for such small work as is required, will be found as good as any. Any joints that are absolutely necessary should be carefully worked so much as possible, glued and dowelled together with dowels and Prout's elastic glue. It must be borne in mind that the pattern-moulder places

*All rights reserved.

the patterns in *green* (moist) sand, and that this mixture causes ordinary glued joints to come undone or expand. Any roughnesses left on the pattern also swell up, catch the sand, and thus destroy the sharpness and beauty of the mould, and therefore of the resulting casting. It is therefore advisable, after having cut the wooden patterns to the highest possible degree of smoothness, to varnish them by means of emery paper, &c., to give it a coating of melted paraffin wax, and polish the surface carefully with a roll of flannel. This rendering the patterns not only extremely smooth but impervious to moisture, so that the pattern does not warp when it is placed in the sand. In order that the pattern should come clean out of the sand and not stick away any portion of the mould, care must be taken that the edges be slightly rounded, so as to give what is technically called *draught*. The possessor of a *lathe* can turn up many portions of the fittings with much greater accuracy and rapidity than one provided with only ordinary tools; but in the ensuing directions the amateur is supposed to possess tools of the simplest kind only.

§ 19. The pattern for the *armature* first demands our attention. When completed, it presents the appearance shown at Fig. 14, *a* being the elevation and *b* the section, on a scale of about half the real size, and consists of a wooden cylinder 1¼in. in diameter, by 3¼in. in length, with a deep channel round the ends and sides. To construct this pattern, get a piece of pine 3¼in. long by 1¼in. wide and ¼in. or ⅜in. thick. Lay this on a table on its wide side, and draw a line along its whole length, just shall divide it into two halves of ¼in. or ⅜in. each. Now, draw a line on each side of this central line, rather better than ⅛in. from it, placed smooth, and free from knots and rough-

a. Fig. 14.

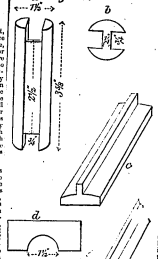

Fig. 15.

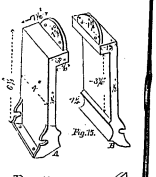

Fig 16

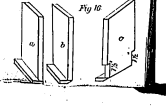

prepared, and care should be taken that the finished pattern should pass exactly through the cardboard pattern, being appreciably neither thicker nor thinner in any part. When this has been effected satisfactorily, a small quantity of paraffin wax or a piece of paraffin candle will add finish to the metal if an iron spoon, and well rubbed into the pattern as a polish with a roll of flannel until it is thoroughly impregnated with the wax; rubbing the iron until it acquires a polish completes the operation, and renders it ready for the foundry. The finished pattern, as shown in section, being 1¼in. wide and about ⅜in. deep all round.

THE DYNAMO: HOW MADE AND HOW USED.—IX.*

By Selsey R. Bottone.

§ 20. THE pattern for the *legs* of the electro-magnet (*field magnets, revolving wrought-iron*) will next require our care. Since the two legs are exact counterparts, the one of the other, so we need only make one pattern, from which, however, two castings must be obtained. Fig. 16 illustrates the form and dimensions of this pattern on a scale of about one-quarter the real size. The dimensions are marked in inches.

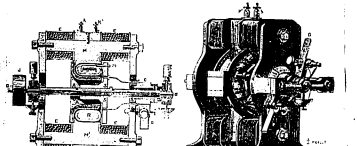
FEIN'S DYNAMO-ELECTRIC GENERATOR.



FEIN'S DYNAMO-ELECTRIC GENERATOR.

M. Fein, of Berlin, patented in May, 1880, a modification of the Gramme machine illustrated above by Figs. 1 and 2, and the details of which are described by the inventor substantially as follows: In dynamo-electric generators constructed on the Pacinotti-Gramme principle, the portions of the electro-magnets exert their inductive action only on the exterior part of the ring, whilst the other portions of the two electromotive wires are of special and only to increase the resistance of the circuit, which gives rise necessarily to a very disadvantageous heating. In order to avoid these inconveniences some generators have been constructed with a flattened ring instead of the more common cylindrical drum, in such a way that the coils can be subjected on both sides to the action of the electro-magnets. By this arrangement the wires, instead of being parallel to one another, are wound obliquely; from which it follows that in order to have on a flat ring, groups of coils of the same total length, and the same number of turns as with a cylindrical ring, it is necessary to give a much larger diameter to the ring. But this increase in diameter produces an increase of resistance, and in order to drive the flat ring, more power is required than for the circular armature. The way by which M. Fein proposed to obviate this inconvenience, and at the same time to secure the most efficient action of the electromagnets, is shown by the form of generator in the illustrations, of which one is a perspective view, and the other a longitudinal section. In the latter the ring is shown at C. It is formed by means of screws which in the drawing are shown in end view, and which is the first point to be noticed. The ends of the wire from each group of coils on the ring pass through insulated holes in the body of the ring, and are led to the commutator C which is placed outside the frame. The current is collected by the two brushes B B. The wound cross current of a number of thin plates insulated from each other, the core is formed of these plates, which are held in the connecting screws. The ends of the latter are connected to the pole-pieces M M, which are bent inwards, as shown in the details of the ring, and these are fixed to the auxiliary pole-pieces A A A bolted to the pole-pieces M, which vertically enclose the ring as shown in the longitudinal section. In this way almost the whole surface of the ring is exposed to the action of the electro-magnets, there being only the small part adjacent to the body S which does not exist in the production of the electromotive force. It is stated that a very simple experiment illustrates the efficiency of this machine; after measuring the intensity of the current it produces in its normal state, if the pole-pieces A A be removed it will be found that the intensity is hardly one-half that which it was before. The advantages claimed by the inventor for this arrangement are: 1. The reduction of the ring are sufficient to counterbalance the resistance of the coils. 2. The reduction of the ring are sufficient to counterbalance the resistance of the coils. 3. The employment of cross currents in practice to receive a variety of small charges for delivery to the screw at the end of the mandrel, which with the exception of the first, is also bored through, so as to allow a small wire to be passed through from behind without impinging on the charge. The system is also claimed to be capable of being used in connection with other machines for the production of electromotive force, as well as for the purpose to which it is more particularly applied by the inventor.

DYNAMO-ELECTRIC MACHINERY.—VIII.*

By Prof. S. P. Thompson, D.A., D.Sc.

(*Continued from page* 562.)

The Dynamo as a Motor.

IN my first lecture I laid down the definition that "by dynamo-electric machinery is meant machinery for converting the energy of mechanical motion into the energy of electric currents, or *vice versâ*."

An electric motor, or, as it was formerly called, an electro-magnetic engine, is one which does mechanical work at the expense of electric energy; and this is true, no matter whether the magnets which produce the field in such machines be permanent magnets capable of steady magnetism or not, even, in fact, of the four kinds of dynamo enumerated successively as a motor, though, as we shall see, some seem appropriately than others. But the machines which are designed to be permanently magnetised, and not of temporarily magnetised iron, all these machines are governed by the same principles; and it is easy, then a mere part of a bar or of moving which is an electro-magnet, and which is such attracts and is attracted magnetically.

Everyone knows that a magnet will attract the soft iron armature of another magnet, and will pull it over, and that the very magnet placed in a magnetic field of force tends to turn round one axis of suspension.

As a matter of fact, a mere coil of wire carrying a current is acted upon when placed in the magnetic field, and is pulled round as a magnet is.

On this very principle was constructed the earliest electro-motor of Ritchie, known as the "rotating spiral," or as a steel spiral of eight segments separated by little letter in readily than a toy.

A great step in advance was made by Jacobi, also in 1838, constructed his multipolar machine; and Froment, in 1844, improved for his electro-motor for driving machine wooden frames, in each of which a dozen electro-magnets were fixed, with their poles being set alternately. Between these, upon a wooden disc, were placed another set of electro-magnets, driven by the ordinary alternating arrangement of the fixed poles were kept in rotation, the moving magnets were kept in rotation, the moving magnets were at the moment of passing the poles of the fixed magnets, by means of a contrivance devised by Jacobi, consisting of two wheels, each of four brass toothed wheels, having pieces of ivory let into the teeth between the teeth for insulation. Froment's was, in fact, a very advanced type of dynamo, and did good work in driving the lathes and machines of one's wood-and-metal factory.

A still earlier rotating apparatus, and, like Froment's, a motor, a man was Dr. Barlow's wheel, described in 1823. This instrument, interesting on account of the theoretical remarks of Sir Charles Wheatstone, is important class of machines, namely, those which have a rotating conical magnet.

A fourth class of motors may be named, wherein the moving part, instead of rotating on axis, is caused to oscillate backwards and forwards. Such oscillations may be of very small amount, as in the case of the tuning-fingers, constructed in 1876 by Prof. Hughes, or may be of considerable amount, as in the instrument of Sir Charles Wheatstone, and in the action of an electro-magnet. Del Negro's motor of 1833 was of this class; it is a steel rod was caused to oscillate between the poles of an electro-magnet, and was connected by a crank and connecting-rod to drive machinery. A double oscillating motor of this type of machine was introduced by Page, who employed hollow coils or bobbins as electro-magnets, which, by their alternate action, sucked down from each end into the coils, and caused them to oscillate to and fro. Motors of this kind form an important class, which has been developed by Marcel Deprez, first formulated by Ohmer, but developed later by Maxwell, to the effect that a circuit acted on a magnetic pole in such a way as to manage the number of magnetic lines of force that pass through the circuit a maximum.

Page's suggestion was further developed by Bourbouze, who employed a number of bobbins, each connected like an arc of a circle, and all together like a horse, crank, fly-wheel, connecting-rod, and even an eccentric valve-gear and a slide-valve. But, for cylinders, we have four hollow electro-magnets for pistons we have iron cores that are alternately sucked in and repelled out; and the valve-gear consists of a commutator worked by dragging a pair of platinum-tipped springs over a flat surface made of three pieces of brass separated by two insulating strips of ivory, serves at every stroke the direction of the currents in the coils of the electro-magnets. It is easily a very ingenious machine, and, in point of efficiency, far behind the best of the modern machines. Unfortunately, it does not do to design dynamo-electric machinery on the same lines as steam-engines.

* Extracted from the Cantor Lectures, delivered before the Society of Arts.

ALTERNATING CURRENT MACHINES.

THEORY AND PRACTICAL FORMULÆ OF ALTERNATING CURRENT MAGNETO-ELECTRIC MACHINES.

NOTE BY M. FELIX LUCAS, PRESENTED BY M. CORNU.*

THE moveable armature of an alternating current magneto-electric machine comprises $N = \mu \times \rho$ equal bobbins, and we group in quantity ν groups of ρ bobbins joined up in series; there are as many possible modes of grouping as there are manners of decomposing N into two entire factors, ρ and ν. The inductor is composed of fixed magnets.

For one mode of grouping we may first impart to the armature a fixed speed of rotation of n revolutions per minute. The effects obtained vary, then, with the circuit. Let I be the intensity of the electric current and T the motive work received by the machine and transformed by it into electrical energy: I and T are two functions of R. Let us designate, on the other hand, by r the resistance (measured, for instance, by means of a Wheatstone bridge) of the system of bobbins included in the circuit. We might express it and r in ohms, I in amperes, and T in horse-power. The principle of the conservation of energy gives first

$$(1.) \qquad (R + r)\, I^2 = 75\, g\, T.$$

In order to obtain a second equation, we may have recourse to experiment. I close the circuit by a conductor of unknown resistance; an electro-dynamometer shows the intensity, I, of the current; the engine makes known the work which it produces and from which I subtract the work (measured beforehand) absorbed by the transmissions and by the movement of the machine when it runs with an open circuit; I thus obtain T. By varying the external resistance from zero to infinity, so as to obtain a great number of corresponding values, I and T, we obtain the elements of a graphic tracing in which we take I for the abscissæ and T for the ordinate. I have recognised thus that the law according to which T depends on I, is represented by a parabola of the second degree which passes by the origin of the co-ordinates and of which the axis is vertical. We have, consequently,

$$(2.) \qquad \kappa\,(I - h)^2 = 75\, g\, (k - T).$$

The numerical values of the three parameters, ρ (resistance), h (intensity), and k (mechanical work), are determined when required from the graphic; as the curve passes by the origin of the co-ordinates, we have—

$$(3.) \qquad \rho\, h^2 = 75\, g\, k.$$

If we eliminate T in the equations (1) and (2), taking into account the formula (3), and considering

$$(4.) \qquad \varphi = q\, \rho\, h,$$

we find that there exists between R and I the very simple relation

$$(5.) \qquad (R + r + \rho)\, I = \varphi.$$

The parameter, φ, is expressed in volts: as the electro-motive force ρ represents a fictitious resistance, to which no consumption of mechanical work corresponds. The two equations, (1) and (2), contain all the laws of the function of the machine for a constant speed of the armature and for a fixed method of grouping.

If we wish to determine directly φ and ρ, we may make two accurate experiments, giving to the resistance, R, two known values, R′ and R″, and measuring the corresponding intensities, I′ and I″. We shall thus have

$$(6.) \qquad \begin{cases} \rho = \dfrac{R'\, I' - R''\, I'}{I' - I''} - r, \\ \varphi = (R' - R'')\, \dfrac{I'\, I''}{I' - I''}. \end{cases}$$

For variable speeds of the armature, ρ and φ become functions of the number, n, of revolutions per minute. By determining experimentally the nature of these functions, n varying from 150 to 850 revolutions, I have ascertained that they are linear. In other terms: The parameters, ρ and φ, increase in direct ratio to n. We have therefore—

$$(7.) \qquad \begin{cases} \varphi = \alpha + \alpha\, n \\ \rho = b + \beta\, n \end{cases}$$

and the formula (5) becomes

$$(8.) \qquad I = \frac{\alpha + \alpha\, n}{R + r + b + \beta\, n};$$

I have verified this formula by a very great number of experiments.

We have now only to consider the mode of grouping of the machine, and experiment has led me to the following observations:—

The series grouping of μ identical systems multiplies by μ the parameters ρ, φ, and r: the grouping in quantity of ν identical systems divides by ν the parameters ρ and r, without modifying the parameter φ.

If, therefore, we designate by a_0, α_0, b_0, β_0, and r_0, the parameters corresponding to a single one of the bobbins, we shall have—

$$(9.) \qquad a = \frac{\mu}{\nu}\, a_0,\ \alpha = \frac{\mu}{\nu}\, \alpha_0,\ r = \frac{\mu}{\nu}\, r_0,\ b = \mu\, b_0,\ \beta = \mu\, \beta_0.$$

The electrical energy furnished by the machine on the external circuit is given by the formula

$$(10.) \qquad 75\, g\, T_e = \frac{N\,(\alpha_1 + \alpha_1\, n)^2\, R}{[\nu\, R + \mu\,(r_1 + b_1 + \beta_1\, n)]^2}.$$

It reaches the maximum when we conform to the relation

$$(11.) \qquad \nu\, R = \mu\,(r_1 + b_1 + \beta_1\, n),$$

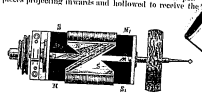
and its value is then

$$(12.) \qquad 75\, g\, T_e = \frac{N\,(\alpha_1 + \alpha_1\, n)^2}{4\,(r_1 + b_1 + \beta_1\, n)}.$$

My experiments, to obtain and verify these various formulæ, were made at the Dépôt Central des Phares, in December, January, and February last, with magneto-electric machines on the De Méritens system.

IRISH'S NEW ELECTRO-MOTOR.

THIS motor has been devised, we are informed, in consequence of the demand for small and effective portable motors. The illustration represents a convenient form for domestic and other uses, where small power only is required, and it is fitted with universal tool holder for brushes, emery wheels, drills, &c., also abscess and friction wheel. Although a hand machine, it may be easily clamped to the bench or table. The field-magnets are simply electro-magnets, with their pole-pieces projecting inwards and hollowed to receive the



armature. The ends of the magnets are coupled together by brass plates, which also form the bearings for the armature. The field-magnets are connected up so that their respective coils come together of different polarity. The armature is of simple Siemens form, but with a twist, which brings one pole opposite N, S, the other pole opposite S, S. The machine is said to act well as a dynamo.

THE E.M.F. OF DYNAMO MACHINES, EXCITED BY A CONSTANT CURRENT.

[A COMMUNICATION.]

IT has been frequently assumed that the E.M.F. is constant for a uniform speed in dynamos, the field-magnets of which are excited by a constant current, and that the fall of potential at the brushes, consequent on increased current through the armature, is only due to the latter having some resistance.* For example, let a dynamo, the field-magnets of which are separately excited, give a difference of potential, V, at the brushes, when a current, C, flows through the circuit. If the resistance in the circuit is diminished, so that a larger current, C_0, flows through the armature the potential at the brushes will be diminished to V_1 and on the assumption that the E.M.F. is constant

$$V + C\, r = V_1 + C_1\, r$$

where r is the resistance of the armature

$$V = V_1 - r\,(C_1 - C)$$

and

$$V_1 = V - r\,(C_1 - C)$$

This means that the potential at the brushes is diminished by a quantity equal to the product of the additional current and resistance of the armature, and from this it might be expected that in any machine

* In connection with this subject I would draw the attention of your readers to an extract from an American paper, which appeared in the ENGINEER for February 2nd, entitled "Regulation of Electromotive Force." In the article referred to Mr. F. B. Crocker ignores everything save the resistance of the armature.

* Comptes Rendus.

an example of machine in which the method of winding makes p and q a minimum for a given number of turns on the armature, the Siemens dynamo might be cited; while, on the other hand, the Bürgin machine might be cited as one in which q, p_1 and also r_1 are excessive for a given number of turns. The armature of the latter machine is wound so as to employ, it would seem, a maximum length of wire for the enclosure of the lines of force, instead of a minimum, and the dividing up of the armature, and separate coiling of each piece, renders p and q very large indeed. Occupying a position midway between these two extremes come the Gramme machine, and generally machines having ring armatures.

In shunt dynamos, it is of special importance that q, p and c, be kept as small as possible, since the potential at the brushes determines the strength of the field, and any diminution due to the foregoing causes, immediately augmentes the fall of potential by weakening the field-magnets. For this reason the curve connecting the difference of potential at the brushes with the current in the lamp circuit for a shunt machine, is never a straight line, but in a well constructed dynamo the curvature for a long range is small, and the slope very gradual. In fig. 3 is shown the curve for a shunt dynamo giving a current of 145 amperes and 50 volts; during the experiments the speed of the machine was maintained uniform at 1,500 revolutions per minute.

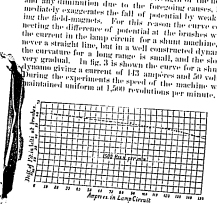


FIG. 3.

The fact of there being a certain E.M.F. expended in starting the current in the coils of the revolving armature does not affect any calculations respecting the commercial efficiency of dynamo machines, since, by commercial efficiency, we mean the ratio of the total energy expended in driving the machine; but it does affect the items of which the commercial efficiency is made up. For example, if in a series dynamo, armature, and r_2 the resistance of the field-magnets, it is generally assumed that the electrical efficiency is expressed by

$$\frac{R}{R + r_1 + r_2},$$

taking for granted, of course, that the E.M.F. of the machine is $c\,(R + r_1 + r_2)$, where c is the current flowing. But it has been shown that the E.M.F. is really $c\,(R + r_1 + r_2 + p)$, where p has the meaning before assigned to it, and the electrical efficiency therefore becomes

$$\frac{R}{R + r_1 + r_2 + p}$$

or somewhat lower than before. On the other hand, the conversion efficiency of the machine is raised somewhat. More of the energy expended in driving the machine is converted into electricity, and less of the energy so converted is utilised.

W. H. ESSON.

speed of the motor. The increased resistance causes a relative movement between the disc and its shaft, and this movement is by suitable mechanism made to impart the adjustment of the throttle valve, or equivalent part of the motor. When the action of one or more of the lights is removed, the strength of current through the shunt circuit, and the relative setting of the disc, become diminished, so as to lessen the resistance to the disc's rotation; and the subtle spring then causes a reversed relative movement of the disc, which brings about the adjustment of the throttle valve, or equivalent part of the motor.

CORRESPONDENCE.

The Electric Light in the Observatory.

As I presume Mr. M. G. Towne is an astronomer, I should have thought that he would have taken in "The Observatory," a publication issued from Greenwich. If he had done so he would have seen an account, in two separate numbers, issued *two years ago*, of an adaptation of the electric light to the Observatory, precisely similar to that described in your last number, only with many more details. That adaptation I have continued ever since, and it is at this moment in full working order. The battery (only four *leclanché* cells) the moveable light (a $\frac{20}{2}$ candle Swan lamp); the switch to change the light into the eye-piece in order to illuminate the wires of the micrometer &c., and the regulation of that light by the depth the elements are sunk in the solution; all is there described much more fully than by Mr. Towne. "Palmam qui meruit."

St. Vincent Beechey.

Hilgay Rectory, *April 5th*, 1884.

Domestic Electric Lighting.

Hilgay Rectory, *Norfolk*, is now completely lighted by the Electric light. A description and some account of the cost and working may not be uninteresting to your amateur readers. The engine is a one-horse nominal steam engine. The boiler, a vertical one, suited to it. The Gramme is a Gramme machine sufficient for sixty 20 C.P. lamps. Much larger, of course, than I require. But as I was fortunate enough to buy it second-hand, though as good as new, for one quarter of its original cost, and, as I can get out of it as much as my engine can drive, it is far more economical than a smaller dynamo. It needs only 600 revolutions for all the lamps that I require. It is most solid and substantial and cannot get out of order. It *never sparks*, and as neither brushes nor commutator ever burn, and it never needs looking after all after its four hours run. I have three lamps in the dining-room, three in the drawing-room, one in my study, two in the hall and staircase, one in each of three bedrooms, one in the pantry, one in the kitchen, one in the back kitchen, two in my parish room, and one in the engine-room or workshop, in all eighteen lamps. I *rare* use all these at once, but it requires the steam to be kept up to 60 lbs. in order to do so, and I never require them all. As a rule the drawing-room and dining-room are not both required at once, except with company, when I use both. The three bedroom lights are turned on and off like gas, to be used only when dressing &c., the two lights in the parish room are only required once or twice a week for an hour. Also all the single lamps have switch holders, so that they can be separately turned on or off as wanted. As a general rule I run twelve lamps, which number I can keep perfectly bright with the steam kept at 45 lbs on the inch. As I also got my engine secondhand and very cheap, the cost of the entire plant did not much exceed fifty pounds. I put up all the wires &c., myself. The lighting is a very complete success.

Now as to economy. It costs me in coals, and the lad who looks after engine and dynamo, 2*s.* 6*d.* a night. That is 2½*d.* for each lamp burning three or four hours. Say one penny per lamp per hour (an over estimate). In one sense this is *far* from economical. It is not dear if you are buying *light*, for each lamp is equal to twelve wax candles. But it is dear, because you are using and *wasting more*, more light than you want. You save nothing by running less than twelve lamps. It is not dear, if you, as I do, in a village where there is no gas, and you hate paraffin, and you take into account all the cleaning and filling of lamps, wicks, glasses, and smells. And it is decidedly cheap if you have company, and want a nice bright, cheerful house, with cool, fresh rooms, and well lighted offices. I may just add that in the bedrooms the lamps are on brackets just over the looking glass, so that the ladies have plenty of light to see they are all right before they go down to dinner.

What is really the greatest drawback to the use of the electric light in domestic lighting is the want of accumulators; for as we do not like to keep our fuel up after ten o'clock, we let him knock off about that time.

St. Vincent Beechey.

Hon. Canon of Manchester.

On the Action which takes place in Ring Armatures.

When the controversy, begun in the ELECTRICAL REVIEW a short time since concerning the action of the Gramme ring, and the action and direction of the magnetic lines of force, I waited anxiously the result, because I thought some useful and valuable knowledge would come of the controversy. I can only say that I was disappointed, and as were others, because it simply ended in personal abuse, and an endeavour to largely advertise a machine as being superior to all others. With the editor's kind permission, I will describe, as well as I can, the means that was always cleared the difficulty, to my mind, as to the real action of the so-called Gramme ring.

I am one of those who hold that the wire in the under part of the ring is not idle, but equally as active as the wire upon the upper part of the ring, minus the cutting of the lines of force of the field magnet poles. I hold this view all the more forcibly because it is the result of actual practice in the every day construction of dynamo-electric machines. But there are certain conditions necessary to bring about this result in the best possible manner, and these conditions have only been found after years of laborious work, careful study and repeated failures in the constructing of such machines.

I am glad to see that Prof. Silvanus Thompson has pretty well come to the conclusion that the Pacinotti form of ring is probably one of the best forms of ring armatures, because it is this form of ring that I have made for some considerable time, being led thereto from a consideration of theoretical principles.

These principles I will now endeavour to describe. *a*, in fig. 1, represents a bar magnet, *b* represents a bar of soft iron surrounded with a coil of insulated wire at its centre, the terminals of this wire coil, *x*, *y*, are attached to a galvanometer; when the bar magnet, *a*, approaches or touches the soft iron bar, *b*, the needle of the galvanometer becomes deflected, and when the bar-magnet, *a*, is withdrawn, the needle is again deflected, only this time in the opposite direction. The cause of this deflection of the galvanometer needle is due to a current of electricity being produced in the wire coil surrounding the iron bar, *b*. This current of electricity being itself produced by the inductive action of the iron bar, *b*, and this inductive action of the iron bar, *b*, is caused by the bar-magnet, *a*. We learn from this experiment three important points—first, that no parts of the wire are idle; second, that molecular change takes place in the bar, *b*; and thirdly, it is the principle of the so-called unipolar dynamo machine, in fig. 2 the bar, *b*, is bent like the letter U. If the wires, *x*, *y*, are attached to a galvanometer, and the bar-magnet, *a*, is made to touch or approach the end of one of the legs, exactly the same effect will take place as in fig. 1. But if we substitute the bar-magnet,

consequence of its automatic action; but those of the Rosum and southern companies considered that the simplicity of the Brady was so great an advantage that they would prefer to renounce the automatic action upon lines of every gradient.

BALL'S UNIPOLAR DYNAMO MACHINE.

Thanks has recently arrived from America a new dynamo machine of the type conventionally known as "unipolar," that is to which the armature is subject to the inductive influence of one pole-piece only. It is the invention of Mr. C. E. Ball, of Philadelphia, and is now being exhibited at No. 46, Kirby-street, Hatton Garden. The small perspective view and the plan on the present page illustrate the machine in this country, while the large perspective view shows a later form of generator, designed to burn fifteen lights, but the difference between the two is merely constructive, both acting in precisely the same way. Referring to the large view, it will be seen that the machine has a double two drums of the Pacinotti type placed end to end, each armature being partly surrounded by a two pole-piece only instead of two, as is usual. The armatures are rectangular bars carrying bobbins wound with insulated wire in such a way as to produce consequent poles, at a distance of about one-third their length from one end. Thus the pole-piece on the upper magnets is, say, of south polarity, and that on the lower magnets of south polarity, and each influences an armature only. In the machine makes the two parallel lines CC constitute the series of the field magnets, and for constructive reasons are left naked opposite the armatures, whether intended to receive a pole-piece or not. The direction of the current is shown on the drawing; leaving the commutator P it passes in succession through the left-hand coil and the middle coil of the bar c, through the coil c', through the external circuit, through the coils c'', c''', to the brush P' and armature P', and by the brush F through the armature P. This arrangement may be modified in various ways; for instance, both the pole-pieces may be of the same polarity, and the armatures may be wound in the same or opposite directions.

The installation at Kirby-street has been placed in the hands of Mr. Robert Sabine, who has made a numbered dynamometrical, photometrical, and electrical tests, of which the following are the more results:

Current in the circuit	15 amperes
Difference of potential between terminals	185 volts.
Resistance of dynamo ...	3·5 ohms.
Speed of dynamo	1650 to 1710 revs. per min.
dynamometer	332 revs. per min.
Indicated pull on dynamometer, less pull when the circuit was open	52 kilos.

From these values it follows that the useful work imparted to the dynamo, less that absorbed by the friction of the spindle, was 3·68 horse-power; and the work actually accumulated for in the outside circuit was 3·32 horse-power, and in the inner circuit 1·35 horse-power. The proportion accounted for electrically was, therefore,

$$\frac{3{\cdot}37}{3{\cdot}68} = 0{\cdot}92,$$

of which

$$\frac{2{\cdot}92}{3{\cdot}68} = 0{\cdot}79$$

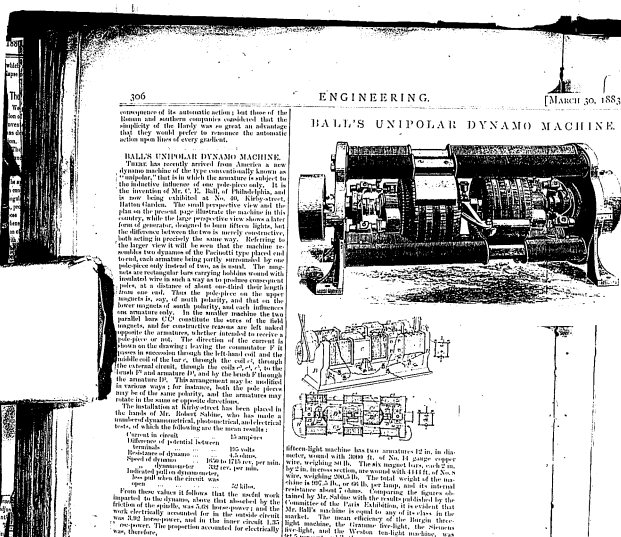
was found in the lamp circuit. Photometric measurements were made with those of the lamps placed upon from the others in a dark recess, the light of the five remaining lamps not being measured. The following mean results were obtained during the observations:

Current in lamps	13·9 amperes.
Potential difference ...	103 volts.
Horse-power accounted for in lamps	0·75 H.P.

The illuminating effects were as follows:

	Illuminating Power.	
Position of Arc with Regard to Photometer.	Standard Candles.	Candles per Horse-Power Accounted for in Lamps.
45° Arc below	1577	1052
22½ ,,	1572	962
Horizontal	1575	1050
22½° Arc above	1533	1047
45 ,,	1533	1047
67½ ,,	1952	2608
90 ,,	1930	2578

The dynamo machine upon which the test was made had two armatures, each 8 in. in diameter, rotating in opposite directions, and each wound with about 10 lb. of No. 14 (American gauge) copper wire. The field magnet coils consisted of 130 lb. of No. 20 wire, the total weight of copper in the machine being 168 lb., which, divided into the number of volts given, gives 17·4 volts per pound of copper. In later machines much better results have been obtained, but none recently done, designed for five lights, having but 88 lb. of copper in it, and weighing only 350 lb. The different light machine has two armatures 12 in. in diameter, wound with about 28 lb. of No. 14 gauge copper wire, weighing 80 lb. The six magnet bars, each 2 in. by 2 in., are also wound, as mentioned with 1111 lb. of No. 8 wire, weighing 1045 lb. The total weight of the machine is 1697 lb., or 56 lb. per lamp, and its internal resistance about 2 ohms. Comparing the figures obtained by Mr. Sabine with the results published by the Committee of the Paris Exhibition, it is evident that Mr. Ball's machine is equal to any of the class in the market. The mean efficiency of the Burgin three-light machine, the Gramme five-light, the Siemens five-light, and the Weston ten-light machine, was 92·5 per cent., while the mean was accounted for in the arcs fed by these machines was 79·5 per cent. of the total. It is difficult to see what advantage can be gained by the use of one pole-piece in place of two, as the magnetic field must necessarily be weakened, and the experiments show that it is not attended by any loss, and that when accompanied by a high speed of rotation it does not necessitate the use of specially large machines.



BALL'S UNIPOLAR DYNAMO MACHINE.

M. JABLOCHKOFF'S NEW ELECTRIC-MOTOR.

Some weeks since we drew attention to the fact that M. Paul Jablochkoff, during a visit to London, had submitted to the inspection of several scientific friends a new electro-motor of his own invention, at once simple and novel. We were enabled to view M. Jablochkoff's machine, but could not at the time publish any facts concerning the principles on which its construction was based. We are now, however, in a position to lay before our readers a few facts concerning the action of this apparatus.

It seems to be established, according to the experiments undertaken on various occasions upon the transmission of power to a distance, that the modern continuous current dynamo-electric machines—Gramme, Siemens, Bürgin, &c.—constitute very efficient electro-motors.

In fact, if they transform 50 per cent. of the power applied to them into electric energy, they are capable of furnishing also in effective work at least 50 per cent. of the electric energy which is supplied to them from terminal to terminal. This return, however, supposes a few secondary modifications in the dynamo-electric machines employed as motors—such, for example, as the arrangement of the brushes, which ought to be set behind the neutral line with respect to the direction of motion instead of in front.

The experiments made with the object of increasing the efficiency of the motor do not seem therefore justifiable, since this efficiency attains at present a figure which it would be difficult to surpass; but besides this question, there is another which it will suffice merely to state in order to make its importance appreciated. What is the actual price of a continuous current dynamo-electric machine capable of supplying $\frac{1}{2}$, $\frac{3}{4}$, $\frac{1}{4}$, 1, 2, 3, &c., horse-power? Practice shows that the actual machines, for equal efficiency, are more economical in cost price as they become more powerful, but that they are very expensive when constructed to furnish the work of only a few kilogrammetres.

We may therefore seek, with little chance of success, for a small electro-motor giving a satisfactory efficiency and low-priced compared to the quantity of work which it can supply, though the problem to be solved has to some extent been effected by the Siemens armature as applied by Marcel Deprez, Trouvé, and by Griscom.

The principal cause of the high efficiency of the Gramme machine, employed as a motor, results from the fact that the changes of direction of the current, and the reversals of polarity, are produced by successive fractions, in a single section at the time, the magnetic force, which must be overcome, is therefore only felt to an imperceptible extent, and one can counteract its detrimental action by a suitable arrangement of the collecting brushes.

In the double T bobbin-motors of Siemens, the magnetic force is less than in the first motors of Froment, Larmoyeur, Page, Lenoirx, &c., by reason of the relatively small dimensions of the magnetic masses submitted to the alterations of polarity; this explains why the return from these motors is intermediate between that of the Froment apparatus and the present continuous current machines. There was one more step to advance in this direction by dispensing completely with the magnetic masses submitted to the change of direction of the current.

At the International Exhibition of Electricity, in Paris held in 1881, M. Bürgin, of Bâle, exhibited an apparatus founded on this principle, and which we described and figured in the ELECTRICAL REVIEW of the 14th January, 1882 (Vol. X., p. 20), translated from *L'Electricien*. We propose to again in order that it may be studied side by side with that of M. Jablochkoff.

It consists of a core of iron, n (figs. 1, 2, and 3), wound round with wire, M, the convolutions of which are wound so as to complete a sphere. This core of iron turns on a horizontal axis, the wires, M, which are attached to the sections of a commutator, C, are traversed by a continuous current from the source of electricity (a battery or a dynamo-electric machine) and polarise the extremities of the core of iron, without reversing the polarities, notwithstanding the rotatory movement of the core.

The sphere formed by this core and the wire, M, M, M, inside a second sphere which is hollow and fixed, and which is wound horizontally a second contiguous wire attached to two brushes of the commutator, C.

In consequence of the reciprocal reaction which takes place between the fixed sphere, B, and the movable polarised core inside, and in consequence of the reversals of current produced in the outer sphere, a rapid rotatory movement is imparted to the core and its axis.

This motor is characterised by the following points:—

(1.) The movable part consists of an electro-magnet, the polarity of which is never reversed.

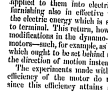


Fig. 1.

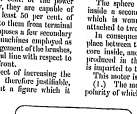

Fig. 2.

Bürgin's Electro-Motor.

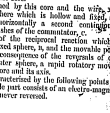

Fig. 3

(2.) The currents are reversed in the fixed part of the motor, and not in the movable part.

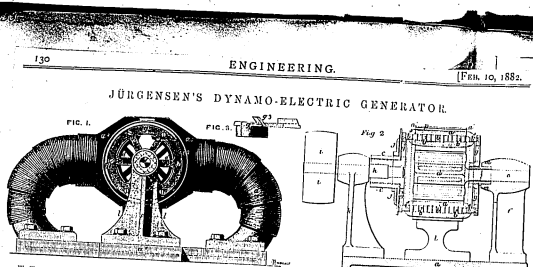
(3.) The movements are produced by the reciprocal action of a current and an electro-magnet, and not by the mutual attraction exercised by two electro-magnets.

There is, therefore, with this mode of construction, no magnetic inertia to overcome, since the system works without reversing the polarity of the core.

The motor of M. Paul Jablochkoff, of which we give an illustration (fig. 4) is due to the same class as the Bürgin machine. It is composed of two bobbins, one fixed upon a horizontal axis in an inclined position, and turning with it, this bobbin is coiled upon a framework of iron, the circles of which form two circular poles (north and south), which, by the arrangement of the commutator, change their polarity twice in a revolution; the second bobbin is fixed in a vertical plane more or less inclined in relation to the horizontal axis of the revolving bobbin; it is coiled upon a non-magnetic frame, and the current which traverses it is continuous in direction. It is the relatively inclined position of the two bobbins which has given the apparatus the name of ecliptic, by reason of the analogy which this inclination presents to that of the ecliptic upon the equator.

The apparatus has arrangements for varying the inclination of the two bobbins so as to determine the best conditions for working; but in the motors for commercial purposes the position of the bobbins, determined once for all, will be fixed and invariable. When studying the mutual action between the movable electro-magnet upon its horizontal axis, which is submitted to the alterations of direction of the current, and the fixed solenoid in which a continuous current circulates, we see that there must result from it a

JÜRGENSEN'S DYNAMO-ELECTRIC GENERATOR.



We illustrate above an interesting form of dynamo-electric machine which was shown at the recent Paris Electrical Exhibition, but which attracted little attention on account of the absence of any attendant to explain its construction. It is the joint design of Professor C. H. Jürgensen and Mr. F. L. V. Lorenz, both of Copenhagen, and embodies several special features in its construction, the principal one being the introduction within the ring armature of an electro-magnet intended to utilise the inner portion of the coils on the ring. The ring consists of a number of thin sections *b* placed side by side, and insulated from each other to prevent the creation of induction currents; by this arrangement very wide rings can be constructed. The sections are held together by bolts passing through them at intervals as shown. Around the ring thus formed the wire is coiled, as indicated in Fig. 2, to complete the armature, which is constructed as follows: To the outer surfaces of the insulating discs *d*, are secured insulated rings *g*, *g* provided with spokes, but each ring is of a somewhat different form. These *g*'s have a small boss, to which is screwed the sleeve *n*, which enters the bearing *a* of the main standard *f*. The other boss *g*' is formed with a long sleeve passing over and secured to the driving shaft *k*. The spokes connecting the ring *g* with the boss are provided with wings *g*', shown in Fig. 3 for the purpose of creating an entire current of air to and keeping the various parts of the machine cool. This is given to them by the pulley *i* mounted on the shaft *k*, which will be seen terminates flush with the inner face of the ring *g*'. The outer electro-magnet *m*, *m* are base-plate at *l*. Each magnet terminates in a wide pole-piece *o*, *o*', the faces of which embrace the armature for nearly the whole of its circumference. In addition to the coils in these magnets increase in volume up to the pole-pieces, the object of this being to obtain a more equal distribution, with less resistance. In order to increase the attraction and increase the steadiness of the machine, the tops of the pole-pieces are held together by an insulated plate *p*, and the latter by two insulated standards *l*, *l*. So far then the machine consists of a cylindrical armature, long at the end of a short shaft, and placed between the widespread polepieces of the two curved electro-magnets, which complete the machine. The space within the cylindrical armature is filled with a second electro-magnet, as shown in Fig. 2. The magnet is carried at the end of the shaft *s*, passing through the bearing *a*, and the sleeve *n* which carries the ring *g*. The magnet consists of two bar magnets at right angles to each other, as shown in Fig. 1, the method of coiling being indicated in the section Fig. 2. At the ends of these magnets are the pole-pieces *r* curved so as to present their surfaces to nearly the whole inner side of the ring. The north and south poles of this magnet are opposite the similar poles of the outer magnets.

The commutator of the machine is shown at *c*, and consists of a series of copper L-shaped bars, one face of which rests on the sleeve to which the driving shaft is screwed, the other face projecting against the ring *g*; the section shows two of these commutator bars. They are, as shown, insulated from the sleeve and ring, and also from the large washer *q*, by which they are fastened to the ring *g*'s. The collecting brushes are not shown, but they are of the usual kind, and may be placed on the bracket *t*. They are capable of adjustment. The current to the inner and outer electro-magnet may be either taken from the main current of the machine, or from a part of the armature reserved for that purpose, or a separate exciting machine may be employed.

The special features in the machine we have described, which was exhibited by Messrs. Jurgensen and Lorenz, are the application in dynamo-electric machines of an electromagnet within the revolving armature, with or without the use of external electro-magnets; the use of annular rings, insulated from each other; the special mode of mounting and coiling the machine by means of the fan or wings attached to the ring at the end of the armature; and the special form of outer electro-magnet. It is to be regretted that no figures are available as to the duty of this machine. Messrs. Jurgensen and Lorenz claim that for its size it is the most powerful dynamo-electric machine yet made, but we have no data on the subject.

Electrical Notes, 1882.

A series of public experiments were made with the Hjelmstrome and Vincent dynamo machine on the evening of Wednesday, February 21, at the offices of Mr. Edwin Brothers, Little Bridge-street, Ludgate hill. The machine was shown feeding 300 Swan lamps, but it is capable of maintaining as many as 600. In addition to this a number of experiments were performed by the Swan, such as boiling water, fusing long lengths of wire, and burning a file. The lamp, so used in the Swan, capable of giving an illumination equal to 100,000 candles.

THE TELEGRAPHIC JOURNAL AND

Electrical Review.

VOL. XI.—NO. 255.

THE "FERRANTI" MACHINE.

ALTHOUGH so much interest has recently been excited in the public mind by the various reports which have been circulated as to the revolution to be effected in electric lighting by the new dynamo-electric machine devised by Mr. Ferranti, the effect on the shares of the other electric light companies has been comparatively nothing worth speaking of. Whether this state of things will continue remains to be seen; but it appears evident that the public is beginning to understand what may be expected from the very best machines that we can ever hope to produce. We may mention here that the system of electric lighting of which we are now speaking, and which is being brought forward under the auspices of the "Hammond" Electric Light Company, is known under the name of "Ferranti" only, Sir William Thomson's connection with the former gentleman being in the alternating current machine of which they are joint inventors. An interesting correspondence, touching the efficiency of the new machine, has recently taken place in the columns of the *Times*, and a Mr. Pertwee—evidently an enthusiastic advocate of the Ferranti system—makes use of what knowledge he possesses regarding the merits of the recent invention to place the Brush machines in a bad light. The secretary of the Anglo-American Brush Electric Light Corporation has replied to Mr. Pertwee's criticisms, very much to the point; however, we can only express a wish that the public will look at such correspondence with indifference, and that they can be actually supplied with genuine figures on which to base their judgment.

It is easy for those conversant with the details of electric lighting to see where comparisons fail, but the general public cannot yet be expected to understand that machines constructed for arc lights will not answer for incandescence lamps. We stated in our columns a short time since that it was difficult to credit the stated low efficiency of the Brush machine for incandescent lighting, more especially if constructed for the latter purpose, and we now find that the results given were obtained from a machine manufactured for arc lighting. Eleven incandescent lamps, of 20 candle-power each per horse-power, from a Ferranti dynamo is not such an exceedingly startling performance as many would imagine, unless we understand by this that the horse-power is that of the engine, and not electrical. We do not know where Mr. Pertwee gets his information from concerning the large Ferranti machine for 25,000 lamps, and upon which he bases some comparative estimates, but we presume that all the various types of these machines are calculated from the experimental one. There is, however, really in existence a dynamo-electric machine, devised by another inventor, which we believe was constructed either for 5,000 or 8,000 lamps. This we hear is, experimentally, highly successful, and as many as 2,000 incandescence lights have at present been connected up with the machine. We are not at liberty to publish further information we have regarding this dynamo, the largest by far yet actually constructed, but as its results will be eagerly looked for we shall endeavour to keep our readers informed as to its performances. To the best of our knowledge, only a small experimental Ferranti machine has yet been tested, and on the strength of this the Hammond Electric Light Company has issued a pamphlet giving estimates for complete installations of the Ferranti system, from 25 to 25,000 incandescence lamps, and from 1 to 65 arc lamps, each system of lighting being from one machine.

We recommend this circular to the notice of all interested in electric lighting, and it may not be out of place to give some particulars here as to the estimated prices of these new machines. One F' Ferranti dynamo, for 65 lamps of 1,500 (nominal) candle-power each, £650, and an E' machine, for 32 similar lamps, £350. For 65 arc lamps, of 2,000 (nominal) candle-power each, one E' machine costs £650, and a machine for 26 similar lamps, £200. Concerning these latter it is stated that three-quarter indicated horse-power is required for each light. It would be premature to express an opinion on this matter at present, but one thing is certain, that if machines to produce the above results can be sold at the prices named, then the ventors of the Hammond Electric Light Company will be well repaid; and the public also will not be slow to take advantage of the greater inducements offered to further the progress of electric lighting.

NEW DYNAMO-ELECTRIC MACHINES

THERE is no doubt but that the consumtaker of a continuous current dynamo-electric machine gives generally more trouble, and requires more attention, than any of the other sorts of such apparatus. The reasons why the commutator requires special care are too well known to electricians to render it necessary for us to dwell upon them; and to do away with this portion of the machine altogether has long been the aim of many inventors.

We do not know of any successful result in this direction as yet, and when an invention professing to accomplish this object is brought forward it deserves more than passing notice.

There has just been issued the specification of H. R. Newton (communicated by Alphonse Isidore Gravier, of Paris). Mr. Gravier's previous ideas are well known to electric light engineers, and the object of the present invention is the production of continuous or of alternating current from a dynamo-electric machine, either in intensity, quantity, or in series, without the use of rubbers, collectors, brushes, or commutators.

The inventor says that by studying the action of dynamo or magneto-electric machines, one general fact which dominates them all is apparent, viz., the necessity for the commutation of the current produced.

Thus if a permanent or electro-magnet be caused to turn in front of a system of bobbins however arranged, currents are induced in these bobbins which change in direction at each half revolution of the inducing magnet.

This is all very well when such alternating currents can be utilised; but should continuous currents be required, recourse must be had to various contrivances, such as commutators, rubbers, brushes, &c.

Besides this, the currents thus obtained and re-arranged are not continuous in the strict interpretation of the word. They are in the same direction, it is true, but they really consist of a series of short currents starting from zero, rising

THE SCHUCKERT DYNAMO-ELECTRIC GENERATOR.

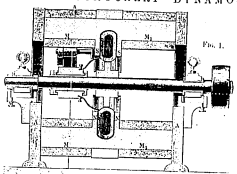


FIG. 1.

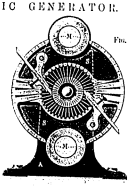

FIG. 2.

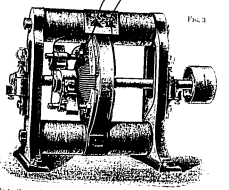

FIG. 3

FIG. 4.

ANNEXED are illustrations of a dynamo-electric generator used considerably on the Continent and in this country, manufactured by the Brush Electric Light Company. This machine, constructed by Mr. S. Schuckert, of Nuremberg, consists of two vertical frames A, between which are fixed the cores of the electro-magnets M M. These cores are cylindrical except at the middle of their length, where they are widened as shown, and formed with a channel groove to receive the revolving armature. The latter consists of a ring built up of a number of plate discs insulated from each other, and covered with coils as shown in the section. This ring is nearly enclosed by the semicircular cores before mentioned as being formed in the middle of the field magnets, and which approach each other within a short distance of the horizontal axis of the ring. The object of this special arrangement is of course to bring a large a number of the convolutions of the armature coils as possible within the influence of the magnetic field. The commutator of this machine consists of a number of metal segments insulated from each other, these segments being connected respectively to the sections of the armature coil. The number of these sections varies from four to one hundred, according to whether the machine is intended for low or high tension, and the end of each section is connected to the corresponding segment by a screw, so as to be easily removed for repair or renewal. In the generator illustrated the commutator is shown within the frame, but in the latest pattern it is placed outside the frame so as to be more readily accessible. The arrangement of coils on the armature, and their connexions with the commutator, are shown in Figs. 3 and 3, which also illustrate the way in which the brushes are attached to the pole-pieces. It will be seen that they are each pivoted on a pin, and are free to move the brush passing through a screw and fixed in position by set screws so as to be easily made of exact adjustment.

As already stated, this generator is in considerable use, and appears to give very good results. It is constructed after several different types, varying with the size, and the purpose for which they are specially intended, for the deposition of metals or the production of the electric light. In no modification these machines are made self-exciting, with commutators on both sides of the armature, about one-third of the current being taken off to excite the field magnets. In another type two rings are placed side by side on the shaft, the latter being adapted leading itself to this arrangement, which, of course, involves the use of two commutators. Although the machine is driven at a high speed in ordinary working there is little or no trouble from heating.

The generator has probably the highest electro-motive force in any in practical use, and for this reason it shows with the finish machine the advantage of being especially applicable to installations in which the driving station is at a considerable distance from the area to be illuminated, but it of course requires a proportionately increased care in handling, and in the manipulation and fixing of the conductors.

THE TELEGRAPHIC JOURNAL AND

Electrical Review.

VOL. XI.—No. 252.

...TIVE-POWER FROM ELECTRICITY.

...ount the idea of obtaining motive-power by the ...ation of electricity is very old, and notwithstanding ...t that we possess at the present time such means of ...ing powerful currents as were quite unknown to the ...s men of electricians, yet the matter does not seem to ...so much attention concentrated upon its ultimate ...n now as is formerly did. This seeming want of interest ...bable, chiefly accounted for by the superior attractive... or the moment, of the electric light, so it is scarcely ...vondered at that the electric-motor is being worked ...y comparatively few. Had our predecessors possessed ...namo-electric machines of our day, the problem of ...ng to a practical and economical end the latent power ...waste forces of nature would have been solved. We ...not, however, lose sight of what has been done by ... Siemens and others of late years towards the practical development and use of electric railways; but the distribution of electric force for light work, such as actuating small lathes, &c., does not appear to have yet arrived at any definite solution. It has been stated over and over again what a boon such an application of electricity would be to the numberless workmen privately engaged in the mechanical trades, and who cannot afford to erect a steam-engine and boiler to supply their motive-power. Such a desirable method of securing an invisible but powerful ally cannot, however, fail to the lot of the British workman until, as in the case of electric lighting, central stations are established for electrical distribution on a large scale. Almost without exception electric lighting companies have the word "power" attached to their titles, yet we cannot call to mind a single instance of the application of electricity for such a purpose by any one company. It is somewhat surprising that an association has not yet been formed in England for supplying motive-power solely. With machines which will reproduce at a distance 60 per cent. of the horse-power developed by the driving engine, surely a profitable business might be insured to any company based on such a project, and we feel convinced that the venture would meet with the most favourable support.

The late Electrical Exhibition held in Paris gave sufficient evidence that such an idea is quite practicable, and it may be that the forthcoming exhibits at the Crystal Palace and the Royal Aquarium may produce something novel in this direction. Although private householders might not at first be induced to "rent" electricity for the purpose of driving the family sewing machine, yet there are innumerable instances of manufacturers employing dozens of these useful domestic articles who would certainly be well content to use electric power for the benefit of themselves and the operatives, who cannot but experience great fatigue in driving such machines throughout the long hours to which they are usually subjected. A company formed for this object would not be under the necessity of purchasing patents, as there are several good and simple motors which are free to every one, and the dynamo-electric machines can be obtained from numerous firms. Such extraordinary speculation has been indulged in during the present year, in connection with electrical matters, that we believe the public would strongly support a genuine movement for the general supply of electric power if kept free from electric lighting altogether. It is probable that the most successful start could be made in certain provincial towns rather than in the metropolis, but in either case the scheme appears perfectly feasible.

TESTING BATTERIES OF LOW RESISTANCE.

By H. R. KEMPE.

THE practical difficulties which are found to exist in carrying out the ordinary battery resistance tests, when these tests are applied to the measurement of batteries or accumulators of low resistance, are being continually experienced; some method, therefore, of overcoming these difficulties may prove useful. One fruitful source of error is no doubt imperfect connections from the terminals of the battery cells not being properly cleaned or screwed up, whilst the resistance of the connecting wires themselves may introduce an error which cannot be ignored when the resistance of the cells is excessively small; for instance, the resistance of a single cell of an accumulator may be as low as ·001 ohm, that is about the resistance, of 12 inches of copper wire of No. 13 B.W.G. or 1·10th in. diameter. Supposing, however, that the proper precautions have been taken so as to avoid such errors in the foregoing we are confronted with other difficulties. It is pretty generally known by those who have had to make practical measurements that in order to take battery tests with anything like accuracy, it is necessary that one measurement be made with the battery connected to a resistance approximately equivalent to the resistance of the battery itself; thus in the well-known "half deflection" method we first connect the battery to a galvanometer of very low (and consequently negligible) resistance, and then having noted the deflection, we introduce into the circuit a resistance sufficient to reduce the deflection to that point which indicates that the current flowing in the circuit has been halved in strength. When this is the case the resistance added in the circuit is the resistance of the battery. Instead of reducing the current to one-half strength, it is sufficient to introduce sufficient resistance in the circuit to produce a definite diminution in the deflection, and then from the true deflection observed, and the resistance added in the circuit, the resistance of the battery can be determined by a simple formula. Another well-known method is to charge a condenser from the battery, and then to note the discharge; a second discharge is then taken with the battery shunted, and then the resistance of the battery is determined by a simple formula. Now, in order that any of these methods may be accurate, it is very necessary that the reduced deflection be a decided one. For instance, if the first deflection on a Thomson's galvanometer, say) be 200 divisions, then the reduced deflection should not be less than 150 divisions, and preferably it should be as near to 100 divisions as possible. Assuming, however, that 150 divisions is sufficient, then this will mean that the battery is shunted by a resistance equal to three times the resistance of the battery. Now, supposing we tried to test a single cell of an accumulator having a resistance of ·001 ohm by this method, then when the shunt is inserted we should have a current flowing through the latter equal to

$$\frac{2 \text{ volts}}{\cdot 001 \times 666} = 500 \text{ ampères,}$$

a current sufficient to fuse, or at least, seriously heat (and

arrangements were made to ascertain the exact number of lamps in the circuit during the observations. They were scattered through the whole district, and could not, of course, be stopped at any given moment after they had been started for the night. We were not able to count the lamps at the time to measure the power generated, and also the difference of potentials between the two poles, but we got at these results by indirect way. We were enabled to measure not only the difference of potentials between the two mains, but the current flowing, and, therefore, we got by means of knowing the energy expended in the wires. Simultaneously with these observations we made others on the mean power of the lamps, so as to keep that constant in our calculations. Of the current which comes out of the dynamo, more or less, can be thrown into the magnets; and, by altering the current, the whole of the lamps can be raised or lowered so that they can be kept constantly at 16-candle power. Experiments with the series of indicated dynamos were taken to indicate the power consumed simply in turning the machine at a normal speed when no current was generated. For that purpose the switches which connect them with the magnets, and the lamps with the mains, were opened, and the engine was run at the speed of 270 to 300 revolutions. The results observed were plotted down as a curve, the ordinates of diagram, where the abscissæ were taken to represent the number of lamps and the ordinates the horsepower. Immediately after that the main switch was closed, the external remaining open. So that the dynamos were taken represented the difference between the two energies—that is, the power employed or consumed in maintaining the current in a full circuit, and also local currents in the coil and armature. That difference was found to be 19·77 horse-power. With these safeguards, then, we found that for 300 lamps we had an expenditure of 42·45 horse-power; for 600, 105 horse-power; for 900, 172 horse-power; for 1,200, 145 horse-power. Deducting the 19·77 horse-power consumed in charging the field and overcoming the friction, a total of 125 horsepower remained as occupied in maintaining 1,200 lamps. The result, therefore, is that, after overcoming the friction, the addition of eight 16-candle lamps makes a difference of one additional indicated horse-power. The efficiency so stated is a compound efficiency—partly of dynamo and partly of lamp. The 16-candle lamps were taken at a current of 0·66 (28) ohms when hot, and the 16 only 1·10 ohms—or one-fifth only half the current and horsepower the latter yield. Deducting 19·77 from 125, we get as the efficiency of the dynamo from the lamp, or, did one not want of time, make accurate experiments to measure the current directly, but we made arrangements for ascertaining what was the actual current going out. We could get this from our diagrams. The observations on the difference of potential between the poles of the machine showed that the machine was generating 105·5 volts as the mean. The resistance of the field-magnets taken as the constant is 6·72 ohms. The magnets are twelve in number, and the coils are coupled each in series and two in multiple arc. Therefore the energy

$$\frac{105{\cdot}5^2}{6{\cdot}72} = 1{,}654 \text{ Watts,}$$

represented by the current in the field is

or two horse-power. The total power was 19·7 horse-power. Deducting from this 2 for friction and 2·2 expended by the energy of the field current, we have 9·5 as waste in local current and in the armature bars. We have, then, on the whole, 17·56 horse-power as ineffective in producing current when the dynamo is running with 1,200 candles. The total horsepower ought to be 125. The efficiency of the dynamo is the difference, or 88 per cent., or nearly 90 per cent. This efficiency increases with the number of lamps, and as the machine will bear working up to 1,200 lamps the external resistance of the circuit, and the armature begins to heat, a slightly higher efficiency can be obtained. Special tests on the efficiency of the lamp, to determine the actual horse-power expended in the carbon, showed that with a current of 0·66 ohm the pressure was 46·2 volts, and with a current of 1·05 volts and the current per lamp 7·4 or 7·5 amperes. The result was 72·63 Watts or 1-10th horse-power in the energy expended in the carbon itself. From the horse-power indicated useful series of facts could be obtained. We were able to plot another curve, of which the abscissæ represented *time* and the ordinates horse-power equivalents, so as to express the work of the engine in horse-power hours. Other experiments in general interest were made at the same time on the efficiency of the boiler. The results, therefore, carried out with very considerable care, show that this dynamo has the power of converting into energy of electric current some 90 per cent. of the energy applied to turn the armature of the machine.

The President said that it was only upon such experiments as these that the public were enabled to form an opinion on the subject. Discussion being invited,

Mr. Hedges said that they did not yet know the exact laws upon which the efficiency of energy took place. He had never seen a satisfactory expression for the work of one of these machines, from which one could deduce the connection of the current with the speed, and the resistance which were the three variables in the problem which the engineer required to solve before he could be thoroughly answerable for the action of these machines. They heard a great deal about the characteristic curve of a machine; here it had been furnished by a series of experiments which only supplied what might be have been known without them. Problems in dealing with current velocity of resolution and resistance ought not to depend on experiment for their solution. He had himself endeavoured to analyse published figures on the subject. One of the chief things which he really wanted to know was, "Is the alteration which occurs in the magnetic field produced by the revolving armature considered as a metallic mass?" This was most important for the practical question of the electric magnetism is one of the factors in the determination of the magnetic force. The method of experiment which had been made by Mr. Siemens and described in a paper given before the Society of Arts in May, 1881. That paper assumed the reduction of the magnetism from what it would be when the armature did not receive

by the field, to be proportional to that augmentation and to the velocity of rotation. But it has since been found out that the velocity of the following machine is greater than the velocity of the driver, a very odd thing indeed, and one which entirely did away with the hypothesis of that paper. Siemens that the magnetism in the armature machine would be increased by the revolution of the armature.

Mr. Mackenzie, Edinburgh, followed with a few remarks on the practical results of these machines as exhibited in actual lighting, contending that frequently the cost of the system was a bar in its adoption.

RECENT PROGRESS IN ELECTRIC RAILWAYS.

[Paper read before Section G, Monday, August 28th, 1882.
By Dr. Fleeming.]

Mr. Ritchie has for some time been struck by the economy involved in an electric system of transport, and has set himself to design an electric locomotive, taking as his type the ordinary steam locomotive. He has taken out all the interior mechanism and replaced it by mechanism appropriated to drive the machine by means of an electric current. The machine which he has designed has been done is as follows:—At a certain station they were driven a set of dynamo machines of the well-known patent of Elihu Thomson, consisting of eight of the ordinary 16-candle incandescent lights. A battery is set up at the central station with mains proceeding out at different points on the railway. The current, when it has entered the circumference of the wheel, passes up into the central hub, and so is taken off by brushes into the dynamo placed in the interior of the engine. Hence it is necessary to have the centre of the wheel insulated from the tyre. The dynamo in the interior are of the same type as made by Mr. Ritchie for lighting purposes. The armatures are wound on the Siemens principle, and the same possibility is preserved in the dynamo of making what Edison calls a large intervening mass of iron. The armature is driven by a pinion which takes teeth of cast in the usual way, can be started or stopped by shifting the current into the dynamo, and by varying the external resistance in the circuit of the field of the dynamo, the engineer or locomotive driver has the power of varying the speed of the engine. Mr. Edison has so far succeeded in his experiments that they can run a train of rolling stock at 30 miles an hour in Menlo Park. The most important question of course is whether this engine is to be at any rate economical than the ordinary steam locomotive, and Mr. Edison's statements as to this are based on the design of the ordinary locomotive of the usual type. In such a locomotive it is not possible to get one indicated horse-power with a less consumption than 9 lbs. of coal per hour, unless special attention is given to the living and running. With careless living it is possible to get it to run at a great deal more in the consumption of the coal, using as low as 6 lbs. of coke through the funnel. But under this arrangement you have to add to the consumption of consumption of the coal from the fire-box of the engine to the central station, at which the stationary engines will be of a far more economical type, and using engineering engines of the best type and taking very careful means to economise the consumption of coal, it can be got down to something like 2½ lbs. per horse-power per hour. Therefore there is in the first place a large saving in coal—though it remains to be seen whether what is thus gained is not lost in the transformation of the energy of the coal into electric current. Careful experiments have yet to be made to ascertain the efficiency of the dynamos used: what proportion of the coal-power is transformed into electric current. Some recent experiments at Messrs. Siemens' Mr. Edison's electric light efficiency. The result, so far as the experiments have hitherto gone, is that 84 per cent. of the power supplied to the electric energy more than 90 per cent. of the power appears in turn there. Then as to the resistance of the circuit, which is the other factor in the question, there is another question. Of course there is a loss of energy in the circuit of the mains, and also a loss due to leakage on the railway by imperfect insulation; but even allowing these losses as 50 per cent. for this, assuming that the Porter-Allen engines give an indicated horsepower of 2½ lbs. of coal per hour, Mr. Edison thinks 1 horse-power required for his electric railway, as against six in driving a locomotive. Hence Mr. Edison thinks we may regard these figures as a reliable indication that an electric railway is a more economical means of realising the energy of coal for obtaining motive from place to place. Another controversy which Mr. Edison sees is for the purpose of enabling locomotives to climb the hills in certain cases where the locomotive has to ascend an incline, as for example greater than 1 in 30 or 1 in 40. Mr. Edison proposes to overcome this difficulty by the use of a rack and pinion.

In the first dynamo, Mr. Edison contemplates the use of a belt, but in the later forms he has adopted an endless screw gearing, which is safer than the belt. In the dynamos which he is using to supply a current from the central station he has adopted the plan instead of doing away with belt and gearing, and making the engine connect to the armature of the machine, so that I think there will be still greater advances in the economy and efficiency of the machine which he has devised.

Dr. Forbes said that the assumption on which the calculations seemed to be based on the locomotive consuming 6 lbs. of coal per horse-power per hour was nearly twice the actual fact.

Prof. Forbes said that much in this paper required very great consideration before an opinion could be formed upon it. They were told that 90 per cent. of the power put into the dynamo was converted into the current, but they were not told how much of current was used up in overcoming the dynamo effective, i.e., in overcoming the internal resistances. That statement was quite distinct from stating that 90 per cent. was being used efficiently. Perhaps about one-half might be used in overcoming internal resistance, so that if they allowed 10 per cent. for leakage and so forth, and a large loss of current in the interior of the machine, it would seem almost impossible to imagine that the cost could be so small as had just been stated.

EFFICIENCY OF THE FERRANTI GENERATORS.

On Wednesday last, in the presence of several scientific gentlemen at Messrs. Fernald, Thompson, and Waters, Limited, a series of tests of one of their generators, designed to feed one thousand Swan lamps, their object being to show the number of lamps which could be maintained at full efficiency per indicated horse-power of the engine. The plant consisted, in addition to the generator, of a 25-hp four semi-portable compound engine, with cylinders 12in. and 23in. in diameter, and 24in. stroke, driving a countershaft from which the dynamo, running at 1,000 revolutions per minute, was actuated. The Swan lamps were arranged in two groups; of these the smaller group contained only sixty, and upon these the photometric and other tests were made, as the total current for all the lamps was so large to be conveniently measured. The larger group contained 960 lamps, but as there was a difficulty in transmitting the necessary power through so many miles of them were thrown out of circuit, and consequently the total number actually in use during the experiments was 840.

The resistance of one lamp as tested cold was 292 ohms, and when hot 106.8 ohms. The standard of efficiency adopted for each lamp was .61 watts per candle, and at this intensity the average illuminating power equalled 1,836 candle power. The conductors leading to the smaller group of lamps offered a much less resistance, proportionately to the filaments, than those leading to the larger group, and therefore the intensity of the light of these lamps would be greater than that actually measured. The total resistance of the 840 lamps, plus that of the 1,120 ohms, and of the leads and collecting brushes, when cold, .065 ohm. This, it is observed, is not quite constant, for as the metallic resistance increases with the increase of temperature, that due to the friction on the surface of the collectors would fall, as they get a better bearing on the rings during the rotation of the armatures. Thus the ratio of internal to external resistance was as .065 to .179 or as 1 to 35.3. This includes the resistance of the leads, which for the greater part of the current was less than 1 per cent. but of the lamps. The resistance of the exciting coil was 2.75 ohms, and that of the field magnets 7.37 ohms, while the exciting current was 22.7 amperes.

Several sets of diagrams were taken from the engines and the mean power developed proved to be 123 horse-power. When the straps were thrown off the dynamo, and the engine and countershaft were running light, the power absorbed was 34.7 horse-power, and if to this be added six horse-power, the estimated amount absorbed by the two heavy leather link belts employed to drive the dynamo, the net amount transmitted to the generator is 82.4 horse-power. Dividing the number of lamps by the power we find that each horse-power maintained 10.19 lamps, a most satisfactory number. Calculating the electrical horse-power by the figures obtained from the test group we find it to be 67.8, or within 15 of the indicated mechanical power.

If, as we understood, the resistance of the leads to the small group of lamps was 11 per cent. of the resistance of the filaments, and the resistance of the leads to the large group was less than 1 per cent., then the difference of potential at the terminals of the lamps of the larger group would be greater than that exerted, and the current would likewise be greater, and hence a higher efficiency would be obtained than appears from the figures, and the electrical horse-power, instead of being 81.8 per cent. of the absorbed horse-power, would be much higher. It would be interesting to see the experiments repeated under still more exact conditions.

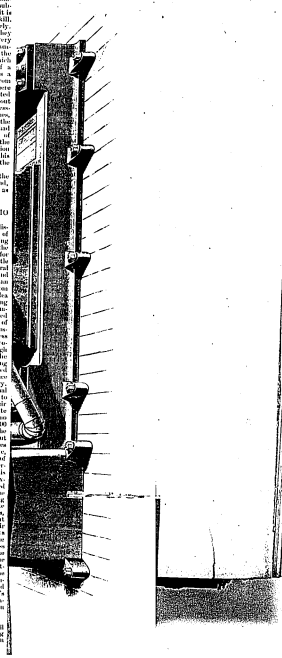
The Ferranti Company, unlike many of their competitors, have chosen to work out each successive improvement which has presented itself before electrifying the criticisms of the public, and hence the plant has sometimes been held that they feared to face inquiry. The figures obtained by these experiments, and the open manner in which they were conducted, should prove that the Ferranti machine, in addition to being exceedingly compact and small for its power, is also economical and efficient. At the same time it need be remembered a consumer is not so much interested in measuring the power absorbed by the generator as the power indicated in the engine required to drive it, as that determines his coal bill, and hence for his purposes it must be said that the number of lamps per horse-power was 6.84, a striking difference, and one which is not always borne in mind in calculations of this kind.

sioners of Montreal as one of a Commission of Engineers to report upon a general scheme of improvements for that harbour, his colleagues being Major-General Newton, of the Corps of Engineers of the United States Army, and Mr. (now Sir) Sanford Fleming, C.M.G., &c., Ottawa, engineer-in-chief of the Intercolonial and Canadian Pacific Railways, Mr. Bell was elected to serve as the chairman of the Commission. The report which they prepared on the subject is now on Blue paper, and the plans by which it is accompanied display a vast amount of engineering skill, which Messrs. Bell and Miller chiefly, though not entirely, devoted themselves to dock and harbour work. They designed and superintended the construction of a very fine bridge over the Clyde at Glasgow, which was completed about a dozen years ago. It is known as the Albert Bridge, an illustrated description of which appears in our tenth volume. Another work of a similar sort was finished a few years ago; it is a bridge over the Kelvin on the road leading from Glasgow to Dumbarton. It may be mentioned here that Messrs. Bell and Miller practically reconstructed the Portland-street Suspension Bridge, Glasgow, about fifteen years ago. They also designed and successfully carried out at least three water supply schemes, one for the town of Grangemouth, another for the cities of Rio Grande and Pelotas in Brazil. We had almost omitted to mention that his London firm of Bell, Miller, and Bell, have in hand the works of the Albert Exhibition Palace, now in course of erection at Battersea. The third member of the firm in this case is Mr. Imrie Bell, Mem. Inst. C.E., who was the engineer for the Jersey Dock Works.

Mr. Bruce Bell was long a leading member of the Institution of Engineers and Shipbuilders in Scotland, serving on the Council as a Vice-President, and as President during the years 1876-78.

THE CENTRAL STATION EDISON DYNAMO MACHINE.

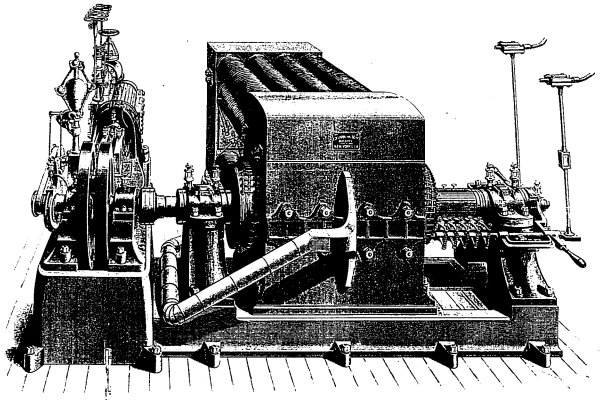
Now that central stations for the lighting of districts are about to be erected in several parts of London, the subject of generators capable of giving powerful currents acquires a new interest, and at the same time the problem of driving them, presents a solution. Hitherto a large installation has been little more than an assemblage within one building of several small ones driven from one or two countershafts, and thus it has come that such plants have presented an appearance of complication, and have further, from the creaking and rustling of the belts, given the idea that an immense amount of wear and tear was going on. It is quite certain that before large areas, employing many thousands of lights, can be supplied from one source, great alterations both in the sizes of the generators themselves, and in the means of transmission, will have to be made before practical success is attained. The earliest and most enthusiastic advocate of district lighting was Mr. Edison, and although his anticipations have not been realised with the rapidity he predicted, yet his system is spreading rapidly in the States, where the company engaged in carrying it out has obtained greater experience of town lighting than any firm in this country, consequently their operations acquire additional interest to English electricians who are about to engage in enterprises of a magnitude far beyond their previous experience, and in view of this we illustrate on the next page the latest type of the Edison dynamo machine, as it appears when designed for feeding 1200 incandescence lamps from a central station. The generator is driven directly from the engine without the use of belts or gearing, and consequently revolves at a moderate speed, about 350 revolutions per minute, while there is no fear of a stoppage from the failure of the intermediate parts. The engine is of the Porter-Allen type, and indicates about 250 horse-power; it is fitted with a Porter governor and an automatic expansion gear, and drives on to a crank-pin fitted between two balance discs. The dynamo follows the ordinary horizontal Edison type, the armature being formed of copper bars upon a core built upof alternate discs of sheet iron and paper, and the field magnets, of which there are twelve, being placed in a shunt circuit. A small fan delivers a constant stream of air to the centre of the armature, where it divides and flows to each end, carrying away the heat generated by the current. Five brushes, each in a separate holder, press upon each side of the commutator, and deliver the current into the two mains shown at the right of the figure, from whence it is distributed through the network of conductors laid all over the district. The point of contact between the brushes and the commutators can be varied, as the whole system is carried on a pivot co-axial with the armature. Mr. Edison's system provides for the connexion of several such machines with one set of mains, and for their regulation according to the demands made upon them.



ELECTRIC LIGHTING IN PARIS.—The Municipal Council of Paris has voted a credit of 200*l*. for the electric lighting of the principal rooms of the Hotel de Ville. The Edison system will be the one adopted.

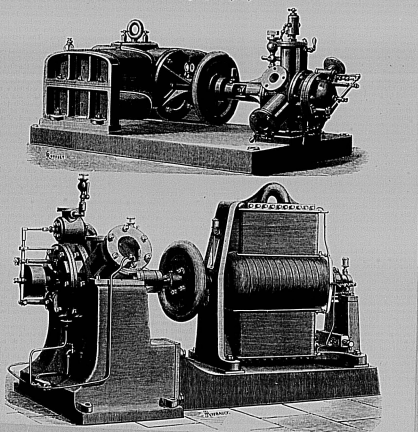
EDISON TWELVE-HUNDRED LIGHT DYNAMO MACHINE, WITH PORTER-ALLEN ENGINE.

(*For Description, see preceding Page*).



DYNAMO-ELECTRIC MACHINE DRIVEN BY BROTHERHOOD ENGINES

(*For Description, see Page* 63).



Engineering, July 20th 1883

MR. PETER BROTHERHOOD'S WORKS.

In our issue of April 27 last, we gave a series of plan and elevations illustrating the new works which Mr. Peter Brotherhood recently erected on the south bank of the Thames immediately below Westminster Bridge, and now we supplement those by a phototype which we publish with the present number, and which gives a perspective view of the interior of the erecting shop. This shows more particularly the central portion, conveying a clear idea of its spacious accommodation. The parts under the galleries of each side, where the machine tools are erected, do not appear in the view. The roof is in four spans, 80 ft. in all, two being over the central erecting shop, and one over each gallery; the length of the part shown in the view being 76 ft.

In addition we give two engravings of the three-cylinder Brotherhood engine arranged to drive dynamo-electric machines. Fig. 1 shows an engine with cylinders 3 in. by 2¾ in., coupled direct to a 6½ Hopkinson dynamo machine, intended to run at a speed of 1500 revolutions a minute and feed forty 5-ohm lamps. Many of our readers are acquainted with the construction of these engines, but we may briefly call attention to the leading features of their design. The chief point which renders the attainment of such high speeds possible is that the connecting rods are always in compression, the steam pressure acting on the back of the pistons to force them forward, and the crank forcing them back. This uniformity of direction of pressure not only does away with all backlash, but greatly simplifies the big ends of the connecting rods, which, instead of having eyes which completely surround the crank-pin end, are segmental bearings of rather less than 120 deg. each. The three connecting rods articulate in the same vertical plane, and abut upon a bush loose upon the crank-pin, where they are held together, for security's sake, by two encircling steel hoops. There are no piston rods, but the pistons are made very long, so as to form guides for themselves. The distribution and exhaustion of the steam is effected for all three cylinders by one valve, situated on a shaft coaxial with the crankshaft. This valve is in the form of a short hollow cylinder, divided into two parts by an internal partition, and provided with ports around its periphery and on its two end faces. It rotates within a steam chamber, and between two faces furnished with three sets of ports in communication with the cylinders; the steam enters one compartment of the valve, and passes through the side ports to one cylinder, while exhaustion is taking place from another cylinder into the other compartment of the valve, which communicates by an opening, near the centre, with the exhaust pipe. By varying the sizes of the ports, the cut-off and compression can be varied to any extent. The governor, which consists of two weights sliding in slots against the pressure of a spring, is fixed on the same spindle as the valve, and operates the throttle valve through a lever shown to the right of the figure. By adjusting the pressure of the spring the speed of the engine can be set to any required velocity.

Fig. 2 illustrates a Brotherhood engine applied to drive a Siemens D dynamo machine, for the production of a naval search light of 50,000 candle power. It would be easy to multiply examples of this kind, as nearly every electric light company has tried these engines, while for many other purposes, particularly for Whitehead torpedoes, they have found an extended application.

THE FERRANTI DYNAMO-ELECTRIC GE

(For Description, see opposite Page).

FIG. 1.

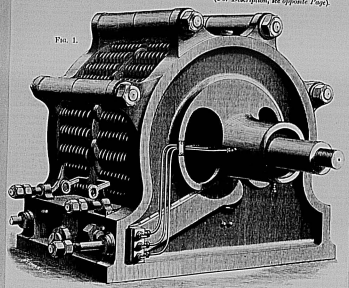


FIG. 2.

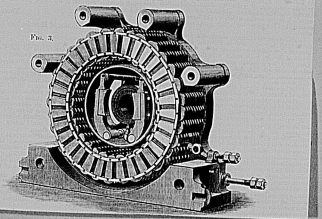

Engineering Oct. 21, 1883.

THE FERRANTI DYNAMO MACHINE.

In view of the great extension of electric lighting which is anticipated upon the passing of the numerous provisional orders now before Parliament, and more particularly in readiness for the needs of their own district of Hampstead, Messrs. Ferranti, Thompson, and Ince have been making more powerful types of their machines, and at the same time have introduced many changes which have resulted partly from their extended experience, and partly from the altered conditions of large machines as compared with small ones.

The dynamo which we illustrate on the opposite page is one of three, and is designed to supply 5000 lamps, each requiring a current having an electromotive force of 200 volts, and an intensity of .33 ampères. It comprises three principal parts, each of which is self-contained. These are the armature (Fig. 2) and the two sets of field magnets (Fig. 3). The former consists of two discs of bosses insulated from each other and from the shaft, and carrying between them an insulated brass ring. To the periphery of this ring there are fastened at equal intervals eight copper strips 1 in. wide and .175 inch thick, and these strips are then bent into the undulating form shown in Fig. 2, each strip making the circuit of the sinuous periphery of the armature twice, and being secured at its outer end to a rivet in electrical contact with one of the discs. Thus as the strips are divided from each other by insulating material, there are eight parallel circuits around the armature, each starting from the internal brass ring and ending, after two complete revolutions, at one of the bosses. At either side of the armature is a collector ring, one of them being joined by a heavy copper connexion (Fig. 2) to the internal brass ring, and the other to the opposite disc, so that the two rings form the terminals of the armature circuit. The current is not taken off by brushes in the usual way, but by solid rubbing pieces (Fig. 3) which embrace both sides of the collector rings, and are held up to their places by springs. The current is led from these collectors down heavy copper bars enclosed in a coating on the outside of the framing (Fig. 1), to two terminal studs, by which it is transmitted to the main leads. The outside diameter of the armature is 26 in., and its speed rather less than 1000 revolutions per minute, at which rate it will furnish about 2000 ampères of current with an electromotive force of 200 volts. As the machine is separately excited from an independent generator, and as its internal resistance is exceedingly small in comparison with that of the outside circuit, to which it will be applied, it follows that the difference of potential at the terminals will be sensibly constant for a given speed, whether there be few or many lamps in action, and that those will burn with the same brilliancy whether a part or the whole of them be lighted. Further as the amount of current in circulation varies exactly with the number of lamps in action, the power absorbed by the machine rises and falls with the amount of light produced, and there is no waste of fuel at the time when the demands for current are but slight.

Although the armature shows considerable improvement in detail from the form in which it originally appeared, yet it is in the field magnet that the most striking alterations are to be seen. There are thirty-two magnets on each side alternately north and south, each north pole being confronted by a south pole, and likewise having a south pole on either side of it. The cores of the magnets are cast with the framing, which, as shown in Fig. 3, is made in halves, and thus by the removal of six bolts the machine may be divided in the centre, and the whole of the internal parts laid open for inspection, while at the same time there is no

ELECTRIC LIGHTING NOTES.

On more than one occasion we have called attention to the improvements effected by Dr. Hopkinson in the Edison dynamo machines. When these first came to this country they were constructed in three sizes, marked Z, L, and K, and designed respectively to feed 60, 120, and 250 lamps. The weight and cost per lamp are given by the following Table:

—	Floor Space per Lamp.	Weight per Lamp.	Price per Lamp.
Z	sqr. ft. 15	lb. 50	£ s. d. 3 10 0
L	11	40	3 0 0
K	.072	33	1 16 0

The L machine was the first to be modified; the diameter of each of its four field magnets was increased 1 in., and two additional layers of wire were put on it. It was then found that 100 volts, or thereabouts, could be obtained at a speed of about 500 revolutions per minute instead of 800 as formerly, without at the same time increasing the consumption of energy in the field-magnet circuit. The total weight was increased by 6 cwt., of which 4 cwt. is cast iron, and 1 cwt. 1 qr. copper wire. A number of these altered machines were placed on various steamships and driven by Brotherhood engines. The improved machine has now gone much further than this; the multiple field-magnets have been replaced by a single one, of round, oval, or rectangular cross section, placed either vertically or horizontally, according to convenience. These magnets are thicker and shorter than in the old machines, and thus the dynamo has been made more compact. The following Table gives the weight and cost per lamp of the new machine:

Lights.	Floor Space per Lamp.	Weight per Lamp.	Cost per Lamp.
	sq. ft.	lb.	£ s. d.
125	.561	21	2 0 0
250	.072	20	1 14 0
500	.037	23	1 3 7

If this be compared with the former Table it will be seen that the new slow-speed Edison-Hopkinson dynamos are cheaper and in every way more efficient than the old high-speed Edison machines.

For description of Jablochkoff's Alternating Current Generator see "Transmission of Power" Page 7/8.

THE MAGNETO-ELECTRIC GENERATOR OF M. DE ROMILLY.

THE magneto-electric machine of M. Wenns de Romilly was patented in France in March, 1880, and the specification under which the invention was secured is a very remarkable one, as it contains the first indication of much that has been done by subsequent inventors. The patent claims three classes of armatures, which are described and illustrated beneath in much detail—the ring armature, the drum armature, and a second form of ring armature, in which the wire is coiled upon a deep and narrow ring, so as to present a laced surface of coils to the fixed magnets, at right angles to the

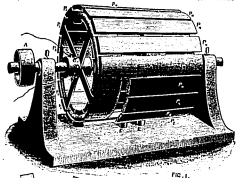

FIG. 1.

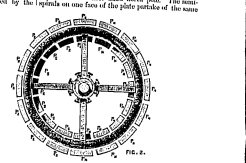

FIG. 2.

FIG. 4.

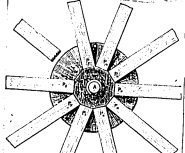

FIG. 3.

axis of rotation. Further, in the principal arrangement described, the field magnets—permanent, not electro-magnets, however—are arranged in a parallel series, and running longitudinally around the armature, and two such series of magnets are employed, one placed without and the other within the ring, so as to utilise both sides of the coils. The armatures described, suggest at once those, long after wards patented, of Gramme, of Allocchi, and of Schuckert, while the arrangement of the field magnets resembles not a little that of Da Meritens and of Jablochkoff; again, the mode of utilising the inner as well as the outer sides of the ring, recalls the recent proposals of Jürgensen and others.

The text of M. de Romilly's specification is as follows: When we cause a metallic plate to pass before the pole of a magnet, perpendicularly to the axis of this magnet, whether the movement is rectilinear, or whether, having the form of a disc, it revolves without interruption before the pole, there are set up in this plate, induced currents perpendicular to the direction of movement, and of the same sign, before and after the passage in front of the pole. This phenomenon, discovered by Arago, explained afterwards by Faraday, and studied in their details by Poisson, by Nobili, Antinori, and Matteucci, have received the name of "magnetism of rotation," "or magnetism of movement." It is the collection and utilisation of induced currents, which are produced when a metal plate passes before the pole of a magnet, perpendicular to its axis—currents which are set up perpendicular to the direction of the passage of the current—that is to say, the collection and utilisation of these currents due to what is named "magnetism by movement," or "magnetism of rotation," which I propose to reserve by the present patent. Induced currents which, up to the present time, have been utilised by employing artificial or natural magnets, have always been produced by the successive reciprocations of a bar of soft iron carrying one or several wires coiled in a direction perpendicular to its axis, and passed in front of the inducto-magnet in such a way as to be magnetised or demagnetised rapidly (as in the Clarke and Alliance machines), or have been produced by the passage, and the successive and rapid interruptions of a current from a voltaic battery in an inductor wire coiled round a bar of soft iron, and itself covered with a coil, in which is set up the induced current (as in induction coils or Ruhmkorff machines). Here it is necessary to pass before the pole of a magnet, or between the two poles of a magnet, a piece of metal of high conductivity—a plate or a copper wire, for example—and to collect the current thus obtained. Experiments made up to the present have been conducted with revolving discs, or with plates passing and repassing before the poles. The current thus produced is very weak, which has rendered it impossible to collect them so as to employ them as ordinary induced currents. What renders the current de feeble is, in the first place, the continuity of the plate or disc, which allows it to be dispersed with extreme facility, so that only a small part can be taken off to demonstrate its existence.

To obviate this inconvenience, it would suffice to pass before the pole a succession of wires, separated from each other, and each extremity of which would communicate with a fixed conductor that would come in contact successively at the moment of their passage before the pole. The current would thus be produced successively on the passage of each separate wire before the inductor pole, without any part being lost, as is the case with a continuous plate. This current, very feeble, when the wire passes before a single pole, is greatly increased when it passes between two opposite poles.

I now assume that it is possible to connect each of these separate wires to the adjacent wire in such a way that the current obtained in one may be in the same direction, and, as it were, a continuation of that which is obtained in the other; in this manner a kind of battery would be obtained, each wire of which would represent an element. To arrive at this, we cause to revolve between two poles of the same name—both north or both south—a plate of soft iron covered with well insulated wire, and coiled in such a manner that the flattened spirals in this iron core are presented perpendicularly to an imaginary line joining the two poles, and perpendicular also to the line indicating the direction of movement of the plate. The soft iron will thus assume a polarity contrary to that of two similar poles. The passage of the plate covered with wire will give rise, on the one side, to a current procured by the wire travelling before a north pole, for example, and a south pole is produced in the plate itself by the influence of the fixed pole, while on the opposite side of the plate there is set up in the coil of wire a contrary current produced by the passage in the same direction before a south pole, resulting from the influence on the soft iron plate, and the other fixed north pole. The semi-spirals on one face of the plate partake of the same movement as the semi-spirals of the other face in a contrary position, referred to a fixed pole, and the pole produced by induction.

This is precisely what is required in order that the currents which have to flow around the core may form at each semi-coil, at each coil, and throughout the series of coils, a continuation of each other. If, then, we suppose a long plate of soft iron thus surrounded, and passing between the similar poles on the two extremities of the coil, being connected by a conductor to a galvanometer, this latter will indicate the presence of a continuous current as long as the plate moves in the same direction, but which will be interrupted when the movement is reversed, and which will take the contrary sign when the plate travels in the opposite direction. The sign of the current can also be changed, by the introversion of the poles, by the direction of the movement, and also by the direction of winding the coils to the right or left. Further, this wire coiled singly can be covered by a second wire wound parallel to it, and brought back over itself, so as to surround the soft iron core several times. Each thickness of the coil superposed will add its current to that of the preceding coil. In this manner, instead of a feeble current, we shall have one, the energy of which will depend on the power of the magnets, on their proximity, on the purity of the soft iron core, on the number of superposed coils, and upon the velocity of movement.

Next to consider an arrangement which will make this process practical, and for which one can collect the induction currents of which we have been speaking. Instead of a soft iron plate, we will take a plate curved in such a way as to form a cylinder, of which the diameter is much greater than the height. We will connect this cylinder by radial arms converging from one side to a rigid shaft passing through the centre of the cylinder; this shaft will rest on bearings in which it may revolve easily. The cylinder, entirely open within, has this only one of its sides partially occupied by the radial arms, that serve to fix it to the central shaft. This arrangement allows of winding longitudinally on the cylinder, a copper wire covered with an insulating material. We will first assume only half the circumference of the cylinder to be thus covered, then we will place in close proximity to one side of the cylinder two magnets, each formed of a bar of steel magnetised; the similar poles of these two magnets—the north for example—are opposite to one another, and allow the iron cylinder, one half of which is surrounded with insulated wire, to pass between them; in this way the wire receives an opposite polarity. We will now do the same thing with the side of the cylinder diametrically opposite, in such a way that

THE CROMPTON SYSTEM OF ELECTRIC LIGHTING.

By reason of its combined power and beauty the electric light was early recognised to be peculiarly adapted for the illumination of railway termini; and the first application of it for that purpose was at the Northern Station in Paris, in 1875. There the superiority of the light over gas was found to expedite the business of the station, and numerous then being soon spread over other stations not only in France but other countries. In Great Britain one of the most important installations was that at St. Enoch's Station, Glasgow,* where the success there attained by Mr. Crompton has now been followed by the lighting of the King's Cross terminus of the Great Northern Railway in Euston-road by a similar arrangement.

The usually large area and high roof of a railway station is favourable to electric lighting by means of powerful arc lamps, for these can be suspended at such a height that the strong shadows they would otherwise throw upon the platform are dissipated, and the blending of the several lights produces a very constant general effect. At King's Cross the power which is lighted within the station consists of two covered bays each 980 ft. long by 105 ft. wide, together with a cab-rank, 40 ft. wide, adjoining the arrival platform. The total area is, therefore, 210,000 square feet, and as it is illuminated by twelve Crompton lamps, the area lighted by each arc is 18,333 square feet, or nearly half an acre. Six of the lamps are placed above the arrival platforms, and six above the departure platform, while two others of greater power are mounted on the east side of the building at the extreme corners of its front to illuminate the side approaches. These fourteen splendid lights are fed by the currents from five Brotherhood steam engines machines driven by a steam engine of 12 horse power nominal.

At St. Enoch's, Glasgow, an area 225 ft. long by 203 ft. wide is lighted by six Crompton lamps fed by six Gramme machines of the A type; but the Brotherhood machine employed at King's Cross confers several advantages on the later installation. When the Gramme or the Siemens generator is used, only one lamp can be placed in the circuit of each machine, and though this arrangement insures that the failure of a single lamp will not affect the others in the series, it involves considerable expense for plant and leading wires. With the Brush generator from five to forty lamps can be supplied by one machine, and the percentage of useful lighting effect is much higher than with the single-light Gramme system; but as all the lamps are connected in one circuit, a fault in any part of it, through defective insulation, or derangement of the apparatus, is necessarily followed by the extinction of all the lights. The arrangement at King's Cross occupies an intermediate position between the Gramme and Brush systems, and unites some of the merits of both. Each Brotherhood machine feeds three arc Crompton lamps connected in series; and the total illumination is produced by combining two or more circuits together so that alternate lamps are fed from different machines. By following this plan the failure of any one circuit only reduces the intensity of the general light one-half, since the lamps in the other circuit are still unaffected.

The Burgin machine is the invention of M. Emile Burgin, of Bâle, in Switzerland, and it was at first designed as a single-light machine. Mr. Crompton, however, saw that it was capable of being modified so as to yield an electromotive force sufficient to supply several lights, while at the same time its small size and simplicity of construction would lend themselves to portability and cheapness. The machine is illustrated on the two following pages, where Fig. 1 is a general view of the side on which the commutator is placed, Fig. 2 is a similar view of the other side showing the driving pulley, Fig. 3 is a view of the armature, Fig. 4 is a part longitudinal section and part elevation, and Fig. 5 a corresponding transverse section.

To get a high electromotive force a high surface velocity of the coils of the armature is necessary, and the ordinary Gramme ring does not admit of this, because the wire of the coils is closely confined and wound so thickly that it is apt to heat with the current. The coils of the Burgin ring, on the other hand, are wound as shown in Fig. 3, which represents the armature of a three-light machine, instead of a single ring as in the Gramme machine, it is composed, as will be seen, of several individual rings B, mounted on the same spindle S, so as to form a kind of barrel. The coils of these rings are, however, all connected in series to the sections of the commutator C, so that the current is collected in the ordinary manner by a pair of copper "brushes." Instead of being a solid circular ring as in the Gramme, each iron core is a hexagonal frame of soft charcoal wire built up into a square bar. Each of the six sides of the core after being covered with varnished tape is wound with a coil of wire in such a manner as to leave the iron cores as bare and bring the general outline of the coil circular. This arrangement will be more understood by reference to Fig. 4, where it is the ring, i the bare cores of the core, and w the coil of wire. It offers several practical advantages. For example, the bare surface of the iron cores next to the poles of the inducing magnets give rise to an intense magnetisation of the ring. Moreover, the simplicity of the winding renders the ring easy to make, and the small number of layers in each coil, together with the free access of air to the exposed surfaces of the wire prevent the coils from being unduly heated by the current. In the Gramme machine there are usually fourteen layers of wire in a coil, whereas in the Burgin there are only five; and the result is that a current which would destroy the Gramme coils has no effect whatever on those of the Burgin machine.

As the six coils on one ring are not sufficient to provide the current required for three lights, eight rings are arranged side by side on the same spindle, and each ring is displaced one-twenty-fourth of a revolution in advance of the last. Fig. 3 illustrates this ingenious construction, which favours the production of a continuous current, for the coils of the barrel which follow one another at this fraction of a revolution are connected in series one after another and their ends joined to the successive strips of the commutator. Thus in Fig. 6, the successive coils of the same ring are not connected in series as in the Gramme armature, but the coil of one particular ring is connected in series to the coil on the next ring which follows it at a distance of one-twenty-fourth of a revolution. This arrangement will be better apprehended by consulting Fig. 6, where a, b, c, d, e, f, are the coils

Fig. 6.

which properly succeed each other in the length of the barrel. They are connected in series, and wires proceed from each to the slips of the commutator. The last coil on the left, a, is properly followed by the first coil of the next set on the right, and it is connected to f, δc., as before. This method of joining the coils obtains throughout the whole ring.

The contact slips of the commutator are made of phosphor-bronze, a metal which wears better than the copper which is usually employed. The two "brushes" B, Fig. 4, which draw off the positive and negative current from the slips C, consist of six short copper combs laid one above another. Each is carried by a bar b which is fixed by means of an adjusting screw a, and a packing piece k; the whole being supported by a bracket c which turns loosely on the spindle f, and presses the brush against the slips of the commutator by means of the spiral spring g. One merit of this arrangement is that the brushes and other parts of the commutator can be readily replaced when worn out.

In the Gramme machine the copper ring required to be mounted on an insulating hub; and as iron cores are all more or less subject to atmospheric influences, the efficiency of the machine is not entirely independent of the climate or country in which it may be placed. But the hexagonal rings of the Burgin armature enable it to be mounted on the spindle S by a hub and spokes of metal as seen at f, in Figs. 4 and 5. The whole armature is light and accurately balanced, and is capable of a high velocity. It comprises 48 coils, each containing 18 ft. of cotton-covered copper wire 0.065 in. in diameter, and the total weight of the wire is only 25 lb. The electric resistance of the whole armature between the two brushes is 1.6 ohms, and the electromotive force or difference of potentials between them for a speed of 1500 revolutions per minute is 155 volts. At 1600 revolutions per minute, the electromotive force is about 206 volts. The speed of the mean diameter of the coils through the magnetic field corresponding to an angular velocity of 1500 revolutions per minute is 2250 ft. per minute. The driving pulley is shown at A in Figs. 1 and 2.

In the Siemens generator the cores of the electromagnets are built up of separate bars of wrought iron, but in the Burgin they form one solid iron casting, which is bored to admit the armature and fitted with a cylinder cover to carry the bobbins. This mode of construction, besides being inexpensive, gives great steadiness of working. Moreover, the mass of iron serves to intensify the magnetic field and the tuned for the armature being truly bored, the bobbins run concentric with the magnetic poles. The cores of the magnets are of oval section, and the heavy pole-pieces f in Fig. 4 are concave at M M, with 10⅛ in. of cotton-covered copper wire 0.141 in. in diameter, and the total weight of wire on the four cores is 140 lb. They are, as will be seen from the figure, coupled in opposite pairs, so as to form two poles of opposite name, between which the bobbins of the armature revolve with great velocity. The electric resistance of these magnet coils is only 1.2 ohms.

The electro-magnets of the Burgin machine can either be separately excited by the current from an auxiliary continuous current machine, or they can be self-excited by the current from the armature. In this case the magnet coils are connected in circuit with the armature coils by suitable terminals, and the total internal resistance of the machine is then 2.8 ohms, or 1.2 ohms less than when excited by 1.6 ohms for the armature. By separately exciting the machine the internal resistance of the circuit is simply the 1.6 ohms due to the armature, and hence a higher electromotive force may be obtained. The machines employed at King's Cross terminus are, therefore, separately excited by Gramme machines of the A type. There are five Burgin generators, and two Gramme machines suffice to excite them, besides feeding several Swan incandescence lamps of the pattern tried in the Pleasley mines, which serve to light the engine-room. The circling current is about 12 webers.

The whole of these seven dynamo-electric machines are driven from a short length of counter-shafting by a semi-portable engine constructed according to Mr. Crompton's designs by Messrs. Marshall, Sons, and Co., of Gainsborough, and similar to that supplied by them to Messrs. Crompton and Co. for the Electrical Exhibition. The engine has a 12 in. cylinder and a 1 ft. stroke. Its nominal horse power is 12, but it is capable of working up to 35 horse power, and at King's Cross when all the lamps are burning it is found to indicate 29 horse power, of which 3½ horse power is absorbed by the engine and gearing. Each of the twelve lights within the station absorbs about 1½ horse power, and each of the six external lights in the station front, some 3 horse power. The five 5 horse power lamps in the engine shed are estimated to absorb about 1½ horse power.

At present only one engine is used, but to guard against the inconvenience of a breakdown, a second of the same type will shortly be placed in the shed, and connected to the countershafting in a similar manner to the present engine. By the aid of a friction clutch, either engine will be put into gear with the shafting instantaneously, so that should an accident happen to one engine the work can be transferred to the other at a moment's notice.

The shed where the generators are placed is situated at a distance of about 252 yards from the nearest point of the station, so that the leading wires are of considerable length. The longest circuit of the internal lamps is about 600 yards, and that for the furthest external lamps 720 yards, including the return wire. The twelve lights within the station are arranged on four separate circuits, three to each circuit, and the two external lights are connected to a separate circuit; but a single return wire answers for all.

Bare copper wire, of No. 8 gauge, is employed, and it is carried on posts from the engine-house on the west over the roof of the Suburban Station. The rest of the terminus is then entered by means of flexible insulated leads, and bare wire supported from the wall by wood insulators is then used to convey the current to the lamps. The six lamps above each platform are fed by two separate circuits, and

But the light from six of the Crompton lights is quite as good as that which was formerly obtained from these gas burners. The twelve lights, therefore, give a much superior illumination, and by the terms of contract with Mr. Crompton the cost is no greater than for gas. The working expense at King's Cross is about 4d. per hour per lamp, including coal, cartage, oil, waste, petty repairs, and attendance. To this must be added the interest on the prime cost of the machines and installation; but as the Burgin machine is comparatively inexpensive the Crompton-Burgin light has an advantage in this respect. A Burgin machine giving eight lights costs about £60.

With regard to the efficiency of the system we may observe that it is higher when the resistance in the external circuit is about double the internal resistance of the machine, a law which appears to quite as good for electric machines in general. Careful experiments made at King's Cross and the Arc Works, Chelmsford, have proved that

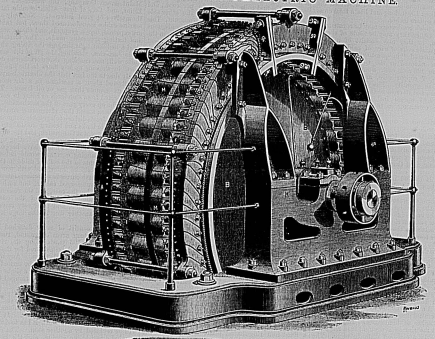
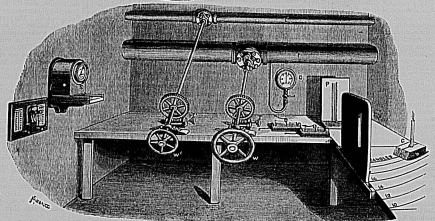
THE GORDON DYNAMO-ELECTRIC MACHINE.





Mr. Gordon's dynamo-electric machine recently completed at the works of the Telegraph Construction and Maintenance Company, Greenwich, is without doubt the largest which has yet been constructed. The object of the inventor was to produce a plant which would take as it were the place of large gas works for supplying light from a central station, and all who have seen the machine and its achievements must admit that he has been experimentally successful.

Mr. Gordon has designed the machine we illustrate to supply from 6000 to 7000 Swan incandescent lights of 20-candle power each; and he has constructed it after a model which may admit of yet much larger sizes being made. This last consideration involves difficulties of its own, for it is a fact too often lost sight of by inventors, that a small machine may work very well, whereas a large machine made on precisely the same plan, will not prove economical. There are several reasons for this; for example, in a small machine, the metal parts of the armature other than the conducting wire upon it, can without weakening the armature be so disposed as not to do any mischief, either electrically or magnetically. But any machine, whether electric or not, which has to absorb say from 600 to 1000 horse power, must have great strength and rigidity in its revolving parts. In the case of a dynamo there would be great difficulty in obtaining the necessary strength of armature, if no metal except the conductor was allowed to move through the magnetic field.

In the new machine the inducing magnets are revolved and the induced coils are fixed, a principle which has been followed before by other inventors. Such a plan allows the revolving wheel in the Gordon machine to be built up of massive wrought-iron plates. A disadvantage of machines in which the armature itself moves, is the difficulty of constructing a suitable rubbing contact for currents of from 1000 to 10,000 amperes or more in strength; but when the magnets themselves are caused to revolve what the magnets themselves are caused to revolve this difficulty does not appear. A further difference in the pattern for large and small dynamos is to be found in the fact that about the same electromotive force is required whether the dynamo be large or small. The armature of a small dynamo large or small. The armature of a small dynamo is wound with a great length of fine wire; but the

meter. The steam gauge indicates the pressure of steam in the boiler of which feeds both engines. The steelyometer indicates the speed in turns per minute of the large dynamos, and the ammeter shows the strength of current in the exciting magnets. One valve wheel, W, works the stop valve of the engine driving the generator, and the other, W, works that of the engine driving the exciting dynamos. The control is effected in the following manner: Two Swan lamps are fitted up on the photometer table, one in the red circuit and one in the blue. By means of suitable switches the current is turned on one of these lamps, and the intensity of the shadow cast by it on the screen of the photometer which is compared with that thrown by a standard candle C. If it is too dim, showing that the lamp is too feeble, the operator turns the valve wheel W of the engine driving the exciter, and admits more steam, thus quickening the engine and the exciting machines. The result is that the exciting currents in the magnets are increased in strength as the ammeter in circuit shows. The intensification of the magnetic field of the generator which ensues, of course causes the generator to go slower, but this slackening of speed is corrected by admitting more steam to its driving engine by working the other valve wheel W. The steelyometer indicates when the old speed has been regained, and the photometer shows that the lamp has recovered its normal brightness. If a lamp should become too bright the same process in the contrary direction is followed out, and one circuit after the other is tested thus by means of the switches. The speed of the generator is kept practically constant, the regulation being effected by increasing or diminishing the strength of current in the exciting magnets. This mode of regulation allows of a great number of lights being put out at a time, and enables the machine to feel few or many. To avoid any sudden change of light in regulating, a slow motion is given to the valve wheels by means of tangent screws T T turned by hand.

THE SCHUCKERT DYNAMO-ELECTRIC GENERATOR.

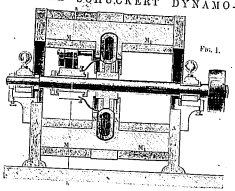


FIG. 1.

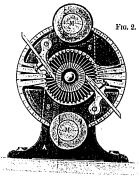

FIG. 2.

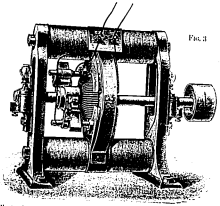

FIG. 3.

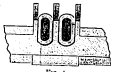

FIG. 4.

ABOVE are illustrations of a dynamo-electric generator used considerably on the Continent and in this country, amongst others by the Brush Electric Light Company. This machine, constructed by Mr. S. Schuckert, of Nürnberg, consists of two vertical iron bars A, between which are fixed the cores of the electro-magnets M M. These cores are cylindrical except at the middle of their length, where they are widened as shown, and formed with a central groove to receive the revolving armature. The latter consists of a ring built up of a number of thin discs insulated from each other, and covered with coil as shown in the section. This ring is nearly enclosed by the semi-circular pole-pieces before mentioned as being formed in the middle of the field magnets, and which approach each other within a short distance of the horizontal axis of the ring. The object of this special arrangement is, of course to bring as large a number of the convolutions of the armature coils as possible within the influence of the magnetic field. The commutator of the machine consists of a number of metal segments insulated from each other, these segments being connected respectively to the sections of the armature coil. The number of three sections varies from ten to one hundred, according to whether the machine is intended for low or high tension, and the end of each section is connected to its corresponding segment by a screw, so as to be easily removed for repair or renewal. In the generator illustrated the commutator is shown within the frame, but in the latest pattern it is placed outside the frame so as to be more readily accessible. The arrangement of coils on the armature, and their connection with the commutator, are shown in Figs. 1 and 2, which also illustrate the way in which the brushes are attached to the pole-pieces. It will be seen that they are each pivoted on a pin, and are free to move the brush passing through a screw and fixed in position by set screws so as to be capable of exact adjustment.

As already stated, this generator is in considerable use, and appears to give very good results. It is constructed after several different types, varying with the size, and the purpose for which they are specially intended, for the deposition of metals or the production of the electric light. In some differences these machines are made self-exciting, with commutators on both sides of the armature, about one-third of the current being taken off to excite the field magnets. In another form two rings are placed side by side on the shaft, the flat form adopted leading itself to this arrangement, which, of course, involves the use of two commutators. Although the machine is driven at a high speed in ordinary working there is little or no trouble from heating.

This generator has probably the highest electromotive force of any in practical use, and for this reason it shares with the Brush machine the advantage of being especially applicable to installations in which the driving station is at a considerable distance from the area to be illuminated, but it of course requires a proportionately increased care in handling, and in the manipulation and fixing of the conductors.

Engineering, Nov. 17, 1882, p. 444

ELECTRIC LIGHTING.

By Dr. C. W. SIEMENS.*

HAVING received the honour of being elected Chairman of the Council of the Society of Arts for the ensuing year, the duty devolves upon me of opening the coming session by an address on a scientific subject.

During the months have elapsed since I was called upon to deliver my last address, the British Association of Southampton, and it may be reasonably supposed that I then exhausted my powers of research, thought and observation regarding the present subject-matter of science, both abstract and applied; that, indeed, I came before you to say a popular farewell, having surpassed myself. Just yet so long is the field of modern knowledge, and that, notwithstanding the great and well-earned reward, its almost daily meetings and lectures, extending for months of the year, possessing specialities for the presentation of opportunities of following up questions of industrial progress to the point of their practical solution.

In glancing back upon its history during the 176 years of its existence, we discover that the Society of Arts was part of the institution to introduce ornament into the industrial arts; that, indeed, the Society of Arts and its offshoots—the Royal Institution, the late Prince Consort, that the first Universal Exhibition was proposed, and brought to a successful issue in 1851; and that it was to the same Society, supported on all important occasions by its annual Premiums, the Prince of Wales, that so many important changes in our educational and industrial systems, which have proved of such numerous to be referred to specifically in the present occasion.

Amongst the subjects to which we have chiefly turned our attention are electric lighting and of the transmission of force by electricity. These together form a subject which has occupied my attention and that of my brothers for a great number of years, and that of my partners, extending as it does to what I believe I may say, considering that at Southampton I dealt with this important subject, scientific considerations involved I need hardly remind you that electric lighting, viewed as a physical experiment, has been known to us since the early part of the present century, and that many attempts have been made to render it generally applicable. The practical difficulties to be overcome in the application of the electric current to the production of light, and the electric current to the production of force, to be mastered by the mechanical difficulty of constructing dynamo machines capable of sustaining, with steadiness, prolonged effect.

The dynamo-machine, which enables us to convert mechanical into electrical force, rendering it available for distribution, disposed of the former difficulty, inasmuch as it properly constructed and sufficiently large, machines of high efficiency converts more than 90 per cent. of the mechanical force imparted to it into electrical activity, 90 per cent. of which may be recovered.

Address delivered before the Society of Arts.

late forces at a moderate distance. The amount of loss, however, does not exceed 20 per cent., unless the conductor is unduly reduced in section, and this is quite capable of being reduced to a minimum by improved modes of construction; but it results from these figures that no great advantage is obtained by the employment of high pressure machines presently in use for this purpose. The only one case where a great economy would result would be in the case of overcoming engines; it has been proposed to employ the electric current for the purpose of distributing power from a central station, and this is quite practicable, but the difficulty of subdividing a small current of high potential, so as to be available for the purposes of motive power, is a very serious one, involving the necessity of a multiplicity of wires and of complicated governing apparatus, which would render the system impracticable, except in cases of very large motive power, as in the working of railways, or in the working of mines, where current are exceptionally high potentials, except where the copper wire would be entirely saved.

The essential point to be attended to in the conveyance of currents is the iron, and for the prevention of inductive action between the wire in such position as to make the whole of it effective for the production of undesired current. These principles, which have been clearly established by the labours of comparatively few workers in applied science, admit of being carried out in an almost infinite variety of constructive forms, for each of which the inventor is prepared to claim originality, thereby giving rise to a great number of nominally different systems of electric lighting, subject in each condition to the right of competition and patent, which, however, is often the subject of considerable litigation, and may be regarded as a purely tentative measure, inasmuch as it is not favourable to the development of any system that would have proved to be really valuable. If this is the case with the electric light, it is still more generally applicable, the license would in all probability be refused, as in the Siemens armature (1856), the Pacinotti ring (1861), and the self-exciting principle (1867), were published by myself and brothers, without any intention of securing a patent, which generally made subject matter of letters patent, which generally appears to have had the contrary effect of what might have been expected, in that it has retarded the introduction of the electric light and machines, because no person or firm had a sufficient commercial interest to undertake the large outlay which would have necessarily be incurred in reducing a first conception to a practical shape. Great credit is due to Mr. Edison for having given to the lighting public the practical solution of many of the forms of construction of the special machines which he has applied to the electric light, and which, when five years ago I first made public for the dynamo-transmitting power to a distance, as a means of working locked upon as more or less whimsical. A few striking examples of what could be practically done by means of electric currents, such as the illumination of the Place de l'Opera, Paris, the occasional exhibition of powerful electric lights, and their application for military and lighthouse purposes, but especially the gradual accumulation of the electric light by Gaudicheau in connection with public feeling; and you may safely say that the electric light was a somewhat sudden reversion of Stock Exchange securities, whose value during the years at the disposal

electromotive force, and 60 watts for their efficient working, the total current required for 64,000 arch lights is 107,200 amperes, and the cost of the electric energy lost by this current in passing through $\frac{1}{10}$th of an ohm resistance, is 25l. per hour.

The resistance of a copper bar one quarter of a mile in length, and one square inch in section, is very nearly $\frac{1}{10}$th of an ohm, and the weight is about 2½ tons. Assuming, then, the price of insulated copper conductor at 80l. per ton, and the rate of interest and depreciation at 7½ per cent., the charge per hour of 1l. would suffice for, when used eight hours per day, 8.15l. Hence, following the principle I have stated above, the proper size of conductor to use for an installation of the magnitude I have supposed, would be one of 46.29 in. section, or a round rod 8 in. in diameter.

MATTHEWS' DYNAMO ELECTRIC MACHINE.

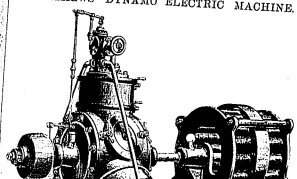

Fig. 1. Fig. 2 Fig. 3. Fig. 4. Fig. 5. Fig. 6.

Fig. 10. Fig. 11. Fig. 12. Fig. 13. Fig. 14.

Fig. 15. Fig. 16. Fig. 17.

MATTHEWS' THREE-CYLINDER ENGINE AND DYNAMO MACHINE.

A novel form of three-cylinder engine, in which increased economy is sought by the application of the Compound principle, is being manufactured by Mr. Herbert Matthews, of Hyde, Cheshire. The cylinders (under fashion radially around the crankshaft, the high-pressure cylinder being the rear one in each instance). In it there works a plunger, which is packed with three rings, while its forward end is joined to a larger plunger working in the low-pressure cylinder, the one cylinder opening directly into the other. A connecting rod couples the lower plunger to the crank. The rods abut upon a segmental bearing, so all are always in compression, some crank-pins. The rods being the shortest necessarily alternating, and lying in a diagonal direction.

For continuous current machines with armatures of the ring described with reference to Fig. 1, where the number of part coils is equal to the number of alternate bars, or equal to twice the number of the same polar faces, the discs are placed in advance of each other as in Fig. 10, so that the pairs of part coils or elements are not at their maximum induction at the same time. For continuous currents with armatures having but one set of bars, the number of spaces are arranged to be less or greater by any even number than twice the number of like polar fields, as in Fig. 17, where the fine radii represented by the dotted circles are nine in number, and the spaces and part coils are sixteen. The inner parts of the coils D' D' are coupled up and connected to a commutator J which is made up of 144 bars, each of the terminals 13 being coupled to nine bars of the commutator spaced at equal intervals, two such connections being shown by the rings M M, which have nine brushes K leading to the bars on the commutator, so that when all the connections are made there will be 144 bars. By this arrangement only one pair of brushes are required, instead of one pair to each pair of magnets as is usual in multi-polar direct current machines.

his electric hoist and new dynamo-electric machines; but we must leave a fuller description of these and some to another occasion. The keys of Messrs. Muirhead Clark, Muirhead, and Co. are very instructive, and we furnish one or two useful hints to makers, for example, in the signalling key of Mr. Saunders, chief electrician to the Eastern Telegraph Company, the contacts are not made by the direct thrust of the clerk's fingers, but by a pair of springs in the rear of the key, and thus no microphonic variation near of the current due to the varying energy of the operator can take place, the rubbing sprung contact is always the same, whatever the force of the taut is always. The testing keys have large easily clerk's fingers. The testing keys have large easily grasped milled terminals for depressing the wires, and the lever resting for clearing. New should be substantially formed of electric. New should be forget the useful practice initiated by this firm of delineating the course of concealed connecting wires in keys and other apparatus by thin white lines inlaid in the ebonite frames and bases, thus initiating at a glance the course and direction of the current.

THE HEINRICHS SYSTEM OF ELECTRIC ILLUMINATION.

In February of last year* we illustrated and described the electric lamps or regulators, and automatic electric candles devised by Mr. Charles Frederick Heinrichs, the characteristic feature of which consists in the employment of electrically curved carbon rods, in the place of the straight, in dynamo-electric machines of both Siemens and Gramme, while at the same time in its most essential features it differs from either and from every other electric generator. Its point of resemblance to the Siemens machine consists (as will be seen on reference to Fig. 1) in the method by which the magnetic field is excited, and in the general disposition of the field magnets; while its point of resemblance to the Gramme machine lies in the fact that its armature is of annular form, and is wound, Gramme fashion, with insulated wire forming a closed circuit. The armature differs, however, from the Gramme ring in its totally different cross section, which instead of being rectangular as in the Gramme machine, is U-shaped, as seen in Fig. 2 and 3, which latter represents a portion of the ring partly wound and having the U-shaped coreing R cut in coils of insulated copper wire C C. The construction of the armature ring will be best understood by referring to Fig. 3, while the general construction and arrangement of the machine is very clearly shown in Figs. 1 and 2. Referring to the latter figure it will be seen that a is a shaft driven on a horizontal axis by the belt pulley p. On this shaft is keyed the boss r r carrying the armature ring r r, which is of very peculiar construction, being of U-shaped section and having wound upon it U-shaped bobbins while during the working of the machine are revolved within an intense magnetic field produced by the electro-magnet excitation coils a^1 a^2 a^3, &c., a^1 a^2 a^3, &c., which are excited by the powerful rectangular magnet-ring bobbins w w w w which form part of the main circuit of the machine. The various armature coils constructed so as in most machines of the Gramme type, with a set of copper segments r^1 r^2 r^3, &c., forming a cylindrical commutator, containing as many segments as there are wire bobbins on the ring; on to which commutators are pressed a pair of collecting brushes by which the currents generated in the armature are transmitted into the magnet coils and external circuit.

It will be observed that a special feature of this machine is the lateral disposition of the polar extensions of the field magnets which are so placed with respect to the sides of the armature as to embrace and be very close to every portion of its external convex surface, and it is this feature which, while considerably increasing the efficiency of the machine,

* See ENGINEERING, vol. xxix., page 161.

HEINRICHS'S DYNAMO-ELECTRIC MACHINE.

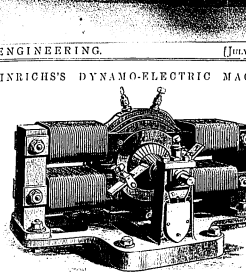

FIG. 1.

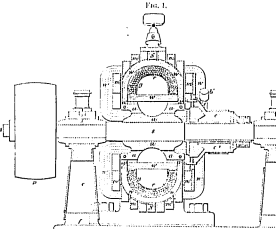

FIG. 2.

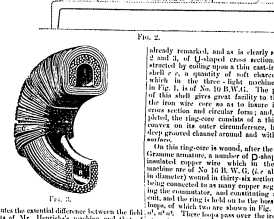

FIG. 3.

constitutes the essential difference between the field magnets of Mr. Heinrichs' machine and that of Messrs. Siemens Brothers and Co.

We will now refer to the construction of the armature ring, which more than anything else is the characteristic feature of Mr. Heinrichs' machine. The iron core of this ring is, as we have already remarked, and as is clearly shown in Figs. 2 and 3, of U-shaped cross section. It is constructed by rolling upon a thin cast-iron mouth or shell $r r_1$ a quantity of soft charcoal iron wire, which in the three-light machine, illustrated in Fig. 1, is of No. 16 B.W.G. (.6 of an inch diameter) wound in thirty-six sections, their ends being connected to as many copper segments forming the commutator, and constituting a closed circuit, and the ring is held on to the boss by six brass cones, of which two are shown in Fig. 2, marked a^1 a^2 a^3. These keep pace over the iron wire core, one at every sixth section, and their ends are attached by screws to the boss $r r_1$. Besides holding the ring-core in its place these brass strips form so many springs from the inside of the ring into the channel, and thus, by ventilating the armature,

"The high efficiency of Mr. Heinrichs's form of armature as an apparatus for inducing currents of electricity from a magnetic field will be understood from the following considerations, and by a comparison of the typical forms of armatures illustrated in the diagrams Figs. 4, 5, and 7. Fig. 4 is a

Fig. 4. Fig. 5.

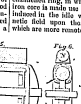

diagram of a Gramme ring within its magnetic field, while Figs. 5, 6, and 7 represent respectively the armatures and magnetic fields of the Siemens, Pacinotti, and Heinrichs machines. In all machines of this general type there must necessarily be a certain proportion of the wire upon the armature which is idle, that is to say, which does not contribute, under the influence of the magnetic field in which it moves, as much current to the main circuit as is taken from it by its own resistance, and it is clear that the greater the proportion of active wire on the armature to dead or idle wire, the greater, other things being equal, will be the efficiency of the machine. M. Antoine Breguet has shown* that one section of the iron ring in a Gramme machine is to screen off, almost entirely, lines of magnetic force from entering the interior of the ring, and from this it follows that all the convolutions of the armature coils which pass across the ring over its inside surface contribute no current, but on the contrary impede those in work, at the same time they add to the total resistance. Referring to Fig. 4 it will be seen that the quantity of wire traversing the ring on its inside is equal to that on the outside. Thus, if the ring be 6 in. wide, in every convolution of the wire there will be 6 in. of wire outside the ring under the influence of the magnetic field, and 6 in. inside the ring protected from the influence of magnetic force, and therefore having no useful effect. In a Siemens armature (see Fig. 5) 10 in. long and 6 in. in diameter, there are about 10 in. of useful line to about 7 in. of wire which, by passing across the ends of the armature, do not in its revolution cut through any lines of magnetic force, and therefore do not contribute to the current generated by the machine. In the Pacinotti machine (treating it as a geometry) the amount of wire under the immediate influence of the magnets N and S, Fig. 6 is very small compared to the rest of the convex of the armature. By adopting the U-shaped section of the armature core (see Fig. 2) and winding the U-shaped bobbins, and these enlarged all over their external surfaces by U-shaped magnet bobbins N N, S S S, Mr. Heinrichs has hit upon a form of dynamo-electric machine which is the most sensitive to think the maximum quantity of the armature circuit in proximity to the inducing influence of the magnetic field with the minimum of idle wire, and therefore the minimum of useless resistance to be included in the circuit; thus if the ring shown in

Fig. 7 be 6 in. wide there will be but 1 in. of idle wire in each convolution to 10 in. of conductor fully exposed to the induction action of the magnets which so nearly surround it. Figs. 5 and 7 are two other forms, suggested by Mr. Heinrichs, of his channelled ring, in which the screening action of the iron core is made use of to stimulate back-currents induced in the idle wire by the action of the magnetic field upon those portions of the armature which are more remote from the inducing magnets.

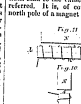

Fig. 6. Fig. 7.

It is a curious fact that Mr. Heinrichs was not led to the adoption of the U-shaped ring for the reasons to which we have just referred, valuable as they undoubtedly are, but from theoretical considerations which are highly ingenious and decidedly interesting, and Mr. Heinrichs attributes the efficiency of his machine more to these theoretical considerations than to the causes to which we have already referred. It is, of course, well known that if the north pole of a magnet N, see Fig. 10, be approached

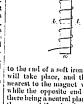

Fig. 11. Fig. 12.

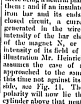

Fig. 10. Fig. 13.

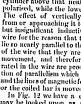
to the rod of a soft iron bar $r r_1$, magnetic induction will take place and the end of the bar which is nearest to the magnet will assume south polarity, while the opposite end will become a north pole, there being a neutral plane $l l$ about half-way between them; and if an insulated wire be wound round the iron bar and its ends joined so as to form a closed circuit, a current of electricity will be generated in the wire every time the magnetic intensity of the bar changes through a movement of the magnet N, or a change in the magnetic intensity of its field of force. Assuming from this illustration Mr. Heinrichs goes a step further, and supposes that the bar $r r_1$ instead of being approached to the same iron bar and coil, but without moving, is extensively but towards its pole, see Fig. 11. The neutral plane $l l$ of no polarity will now lie through its axis, and the left cylinder above that neutral plane will be southerly polarised, while the lower half will become north. The effect of vertically subdividing the magnet from or approaching it to such separate would have the same influence upon the bobbin of wire for the reason that the lines of magnetic force are nearly parallel to the plane of the convolutions of the wire that they are not cut by them in their movement, and therefore the only currents generated in the wire are produced by the slight aberration of parallelism which may exist between the coils and the lines of magnetic force when either the magnet or the coiled bar is moved in a vertical direction.

In Fig. 12 we have a condition of things which may be looked upon as a special case of Fig. 11. In this case the bar is bent round into a continuous ring, and the magnet poles N N S S are curved concentrically with respect to the ring, face again, for the reason given in reference to Fig. 11, but small inductive effect will be produced upon the wire before by the vertical movement of the two pole-pieces N S and N S, although rather more than in the case illustrated in Fig. 11, for the reason that as in the position shown in Fig. 12 the lines of magnetic force are, like the convolutions of

* See ENGINEERING, vol. xxix., page 154.

the coils, more or less radial to the ring, a vertical motion of the pole-pieces will cause certain lines of magnetic force near their outer extremities to be cut by a few of the convolutions near them, and electric currents will, therefore, be generated. But such a movement is in no way analogous to the action of a Gramme machine or apparatus of that type, each of this armature ring within the magnetic field, whereby a lateral or sectorial displacement of the convolutions of the armature takes place, thereby cutting through the nearly radial lines of magnetic force in every portion of their revolution.

Mr. Heinrichs's theory of the action of the Gramme machine is illustrated by the diagram, Fig. 13, which represents a Gramme armature with its commutator and brushes revolving in a direction indicated by the arrows within a magnetic field produced by the magnetic pole-pieces N N and S S. Assuming that in a solid iron ring of the Gramme form, the influence of each of the magnets N and S is to induce polarity opposite to itself on the parts of the ring nearest to it, and polarity of the same sign on the parts more remote, it would follow that if the ring were not in motion, its polarity would be distributed as is shown in Fig. 12, that is to say, the outer circumference of the upper half of the ring would be inner magnetic strength of its lower half would have south polarity, while the inner circumference of the upper half and the outer circumference of the lower half would assume north polarity



and the neutral region of the ring would be cylindrical surfaces passing through the circular axis of the iron ring. The moment, however, that the ring is rotated upon its principal axis (according to Mr. Heinrichs) a sectorial deflection of polarisation is set up. We may, for the purpose of this explanation, call the magnetic influence of N upon a in Fig. 10 *longitudinal* polarisation, and that in Fig. 11 *transverse* polarisation, the motion of the magnet in both cases being in a vertical direction. If however the magnet N in Fig. 11 be similarly displaced, that is to say, if it be moved in a direction parallel to $l l$, it will be found that all less taken an appreciable time to become established, and transverse polarisation, and may be termed for the purpose of this argument *sluggish* polarisation, the polarity of the more remote parts sluggishness, so to speak, behind that of the others in that existing in a plane the bottom more or less diagonal. Now, just as Fig. 12 represented a special instance of what was described generally under Fig. 11, on the assumption of a *vertical* displacement of either magnet or bar, so Fig. 13 may be regarded as a special instance of Fig. 11, on the assumption of a *lateral* displacement of either of the principal parts. In this case the neutral surface will become a spiral (dividing the ring into two parts), whose obliquity with respect to the circumference of the ring will be dependent upon several causes, the principal of which are the speed of rotation, the strength of the magnetic field and the magnetic capacity, or rather the rapidity of magnetic induction of the iron ring.

According to this theory that portion of the ring opposite p', which has been for a considerable portion of its revolution under the influence of the pole S S, will be almost entirely of north polarity; but immediately after passing under the influence of the south pole-piece N N, opposite l'

THE HEINRICHS SYSTEM OF ELECTRIC LIGHTING.

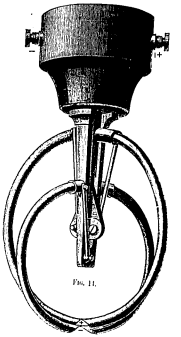


FIG. 11.

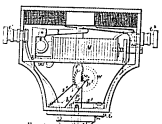

FIG. 15.

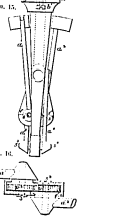

FIG. 16.

pencils, which is in its turn determined by form of construction and method of attachments of the carbon holders. Of this class the lamp known as the Hopfel-Regulator, which we figured and described some three years ago,* may be regarded as the general type; but Mr. Heinrichs's lamp possesses this advantage over that of M. Hopfel, that as the carbon rods, although carried, about against one another so as to be in contact at their point of contact there is no tendency to jam and become fixed, as must sometimes be the case with the V form of axial intersection adopted in the Hopfel regulator.

The general principle of Mr. Heinrichs's new lamp is identical with that we described in our issue of the 20th ultimo, that is to say, the arc is formed between the point of abutment or contact of one pair of circularly curved carbons, and the corresponding point of another similar pair below it, the lower of the two circles having perpendicular to one another, as shown in Fig. 11; the upper pair are positive, being connected to the positive pole of the dynamo-electric generator, and the lower pair are negative, being in electrical connection with the other terminal of the machine. The feed of the carbons requires no mechanical appparatus such as clockwork or gearing, but is maintained solely by the mechanical wasting away through the consumption of the carbon rods at their point of contact; the rods falling together by their own weight, as the carbon at their point of contact is dissipated under the action of the current.

While the feed of the carbons is determined by the consumption, the regulation of the length of the arc is effected by electrical means, the strength of current flowing at any one time determining, by the simple contrivances to which we shall next refer, the degree of approach or of separation of the carbon rings.

By reference to Figs. 15 and 16 it will be seen that the upper or positive pair of carbon holders *a*' and *a*'' are pivoted at the points *c*' and *c*'' to two small equal-sized pinions *p*' and *p*'', shown in the detached plan Fig. 16, which by gearing into one another cause the swing of the arms *a*' and *a*'' equal and symmetrical on each side of the vertical axis of the lamp. A similar method of pivoting is adopted for the arms *a*⁴ and *a*⁵, which are the holders for the pair of lower or negative carbons. The geared pinion of the upper pair are attached to the rod *f*, which is in its turn suspended from the long arm of the bell-crank lever *l*, of which the short arm is the armature of an electro-magnet M, which when the current passes through the lamp by attracting the armature *i* lifts the rod *f*, and with it the upper pair of carbons separating them from the lower pair, and thus establishing the arc. To prevent the lifting taking place with a sudden jerk, which might set the lamp jumping, the rod *f* is at the same time the adjustment of other lamps in the circuit, Mr. Heinrichs has adopted the very simple and ingenious checking apparatus shown at *d*'. This consists of a small rack forming part of the rod *f*, which gears into the small pinion *p*', on which is the large notched tooth-wheel *w*, against the teeth of which presses the light click spring *c*, and prevents any sudden vertical movement of the rod *f*, to which the upper carbons are attached. The lower or negative pair of carbon rods are fixed to and in electrical connection with the frame *D*, which while being insulated from the case of the lamp and positive terminal *p*, by the ebonite washer *i*, is connected by a wire to the negative attachment screw of the lamp *l*' seen to the left of the figure.

It is a coil of insulated German silver wire, whose resistance is about equal to that of the arc, and its use is to prevent the other lamps in the same circuit being affected by the vertical movement of the rod *f*, as the arc of the lamp of which it forms part; for the moment that the current ceases to flow from one pair of carbons to the other it is shunted through it by a very simple contrivance, and as the resistance offered by the coil is practically equal to that of the arc which it supplants the strength of the current throughout the rest of the circuit is not affected by the interruption, and it enables one of the lamps to be extinguished without affecting the others of the same series. The arrangement by which the circuit of R R is substituted for that of the arc when the latter is interrupted, is shown in Fig. 15. On the rod *f* is fixed a projecting pin *p*' which, when the rod drops, brings the contact spring *s*' against the contact screw *s*', which is connected to *D*, and by the wire *h* to the negative terminal. The same action brings the two pairs of carbons together, and in this position a current battery at *C* has two courses through the lamp open to it, one through the resistance R H, and the other through the carbons and through the magnet coils M; the latter portion of the circuit across the carbon to be separated by the lifting of the rod *f*, the arc is thereby established, and the pin *p*' rising with the rod *f* releases the spring *s*' from the screw *s*', thereby cutting the resistance R H out of the circuit and allowing the whole current to pass through the carbons and the arc.

Fig. 16 is a diagram showing the very simple and ingenious method of construction of the pair of pivoted points of the radial carbon holders *a*' and *a*''. In this figure it will be seen that the two pinions *p*' and *p*'' which are geared together are rigidly attached respectively to the radial arms *a*' and *a*'' turning on the pins *c*' and *c*'', which are fixed to opposite sides of the little framing, and the pinions being so proportioned that when pivoted against their respective stops the pinions are in gear and the rods are in their proper position, the axes of their carbon holders lying in the same vertical plane.

Mr. Heinrichs constructs his carbon rings by horizontal compression between dies, the diameter of the circles before they are cut in half varying from 10 in. to 14 in. With carbons of circular cross-section Mr. Heinrichs makes the positive carbon rod 13 millimetres diameter and the negative 11 millimetres, and the length of time which such carbons will burn varies from 20 to 30 hours, according to the diameter of the rings, or rather, the length of curved carbon rod employed—a continuance longer by many hours than can be required in actual practice except in the most exceptional applications.

The carbons, as we have noticed above, are consequently horizontally in dies, this system being more suitable than the longitudinal compression or "squirting" through a circular orifice in a compression cylinder, which can, however, by giving to the rods a curved form, be applied with equal facility to the production of curved carbons as to that of straight pencils.

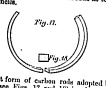

Fig. H.

Fig. N.

The latest form of carbon rods adopted by Mr. Heinrichs (see Figs. 17 and 18) is of rectangular cross section, measuring 14 millimetres by 12 millimetres, the sectional area being about equal to the ribbon form of circular section. Fig. 17 will show rather than any description the mutual positions of the longer and the shorter side of the cross section.

Mr. Heinrichs's rectangular carbon, and Fig. 19 shows a cross section of one of the carbons. This form of carbon presents several facilities in manufacture which has been admirably worked out by Mr. Heinrichs, one of the most important of which is the facility with which the rings can be compressed to any required density—a result not so easily attained with the circular cross section.

Mr. Heinrichs's new lamps work with admirable steadiness, and when enclosed in opal or ground glass globes produce a brilliant, well-distributed light, being remarkably steady notwithstanding the irregularities of the engine and the countermotion in the speed of the generator. From our own experience of the working of Mr. Heinrichs's system we are inclined to think that it must in time occupy a prominent position among systems of electric illumination, and it is much to be regretted that so interesting and characteristic a system, and one which is so successful in working, is not one of the competing electric lights of which there will be many in the coming Electrical Exhibition at Paris.

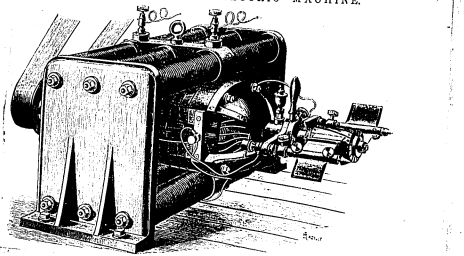
THE WESTON DYNAMO-ELECTRIC MACHINE.



The Engineer
London, July 13, 1881.

The Mather Dynamo-Electric Machine.

An illustrated and descriptive circular and price list of the Mather dynamo-electric machine, which was recently seen us, contains considerable information of a valuable nature to those interested in this class of machines. The pamphlet comprises something over 30 pages, and is handsomely illustrated, containing, besides a number of woodcuts, two perspective views of different machines by the albertype process, which is a modification of the photolype process. The Mather dynamos are intended for electric lighting, electro-plating, electrotyping and similar uses. A rather full description is given of the Mather "F" machine, "besides a brief one of the "ring machine." The pamphlet closes with a price list of the machines, which are made in a number of different sizes, including the prices of their different parts. Among a list of references we notice the names of many well-known electric establishments and other manufacturers. The Mather dynamo-electric machines are manufactured by Mr. A. H. Eddy, Hartford, Conn.

THE WESTON SYSTEM OF ELECTRIC LIGHTING.

The name of Mr. Weston has long been before the public as the inventor of one of the most successful dynamo-electric machines that has been introduced for electro-plating, and we believe at the present time the greater bulk of the largely increasing industry of nickel-plating is performed by Mr. Weston's machines, which in general principle are very similar to the dynamo-electric machine of M. Lontin which has been described in these columns.* The lighting machine of Mr. Weston with which we have to do in the present notice has however nothing in common with the plating machine of the same inventor, for while it has points of resemblance in certain of its details with the machines of Siemens,† Gramme,‡ De Meritens,§ Hiorth, and Manby,‖ it is distinctly original and cannot be confounded with any one of them.

The general external appearance of the machine, which is shown in Fig. 1, on account of the distribution of its field magnets, bears a slight resemblance to one form of the Gramme machine. These magnets consist of six horizontal cylindrical electromagnets, six above the axis of rotation of the armature, and uniting in a single upper pole piece, and six below the armature uniting in two lower pole pieces, the two polar extensions having opposite polarity. The coils of these magnets are connected together in series, and the whole current generated by the machine is transmitted through them, thus producing an intense magnetic field, within which the armature is rotated at a speed of about 1200 revolutions per minute. Those parts of the pole pieces which embrace the armature, instead of being solid and continuous as in those of the Gramme machine, are cut into a series of tongues. These are shown marked T T T, T' T' T', &c., in Fig. 2, which is a diagram of the disposition of the pole pieces, as would be seen from one end of the machine if the magnets M M M and back plate were removed. It will be noticed also that the space between the two pole pieces is wider in the middle than at the two ends of the armature A A, the length of the tongues measured from the magnets decreasing from the centre towards the ends by a sort of elliptic curve. Mr. Weston states that by this arrangement greater regularity of current is secured, the inductive effect of the magnets upon the coils of the armature during its rotation taking place from the centre towards the ends and *reversed*, instead of simultaneously throughout the whole of any one section of the armature wire. The object of the slits in the pole pieces, whereby the latter are divided into a series of tongues, is twofold. In the first place, it effectually prevents cross currents being induced in the pole pieces by induction from the armature; and in the second place, the arrangement materially assists the ventilation of the armature and magnetic field, and thus prevents the machine from becoming overheated.

The armature of the Weston machine is of very peculiar construction, and although it bears some what of a resemblance, when wound and in its place, to the Siemens armature, the construction of its iron core and method of winding is very different. The core of the armature, like that of the Maxim machine, is compound, being built up of a number of iron discs all in form peculiar to itself. One of these discs is shown in Fig. 3 and consists of a disc of iron, shaped like a spur pinion, and having around its circumference sixteen projecting teeth and as many notches. The core of the armature is constructed by threading thirty-six of these discs upon the driving shaft of the machine with small separating washers between, so that there is an air-space between each washer and his neighbour equal in thickness to the thickness of the washer. When the core is completed by the addition of solid end-pieces of a diameter equal to that of the discs, measured across the bottoms of the notches, the whole presents generally the form of a cylinder with hemispherical ends and having a series of sixteen longitudinal grooves cut in its circumference parallel with its axis and a number of smaller transverse grooves between the discs and perpendicular to the longitudinal furrows. Into the sixteen longitudinal grooves are wound as many coils of insulated copper wire, the method of winding being similar to that in the Siemens armature, that is to say, it is laid along one groove across one end and back by the corresponding and diametrically opposite groove on the other side. By this peculiar method of construction it is obvious that the ventilation of the armature is exceptionally well secured, for not only is it hollow, but it is provided with sixteen openings from the inside to the circumference by every disc of which it is composed, or 576 openings in the whole armature; and, as the ends are also provided with openings, a continuous stream of air is, during the working of the machine, constantly being driven through the orifices of the armature and between the spaces of the poles into the outer air.

The commutator which is shown in Fig. 4 is similar in principle to the commutators used in the Siemens and Gramme machines, but its construction differs from them in the fact that the various segments of which it is composed are arranged helically on the shaft, and are separated by air spaces instead of by solid insulating material. The object of this helical disposition of the copper strips of which it is composed is that the rubbing edges of the collectors or "brushes" B (Fig. 5) are, in all positions of rotation of the commutator, in contact with two of its segments, thus insuring greater uniformity to the strength of the current.

Fig. 4.

The collectors or brushes B, of which there are two (diametrically opposed to one another), are made up of ten or a dozen thin curved plates of elastic copper cut by slits into three tongues, and are held against the commutator that the edges of the whole bundle press against the copper segments rotating beneath them, and the brush holders are like those of the Maxim generator, mounted upon a swing frame by which the strength of the current and of the magnetic field can be adjusted by setting the collectors by hand to positions of greater or less efficiency. This arrangement is very clearly shown in the general view of the machine, Fig. 1.

The Weston system is a complete one in itself, that is to say it has both machine and lamp peculiar to itself, and in the succeeding diagrams we give the form and construction of Mr. Weston's lamp, which gives the most highly satisfactory results, regulating itself with extreme accuracy to the strength of the current, and producing a perfectly steady white light. Fig. 5 is a general outside view of the lamp, and Fig. 6 is a diagram illustrative of its very

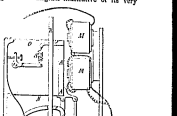


Fig. 6.

interesting and ingenious regulating mechanism, which is contained within the small dome-covered box shown in the upper part of Fig. 5. Referring to Fig. 6, it represents the rod carrying the upper carbon, which when in current is passing, slides freely through the clutch lever C, and therefore allows the upper carbon to rest on the lower. M M is an electro-magnet of peculiar construction, and A A is an armature capable of motion to and fro in a vertical direction only, being supported by the two parallel flat steel springs S and S1, which are firmly attached at their further extremities to the framing of the lamp. It will be observed that in its position of rest the upper end of the armature is just a little below the lower edge of the upper pole of the magnet, so that the action of a current being sent through the magnet coils would be to cause the armature A to be attracted vertically thereby lifting the end of the clutch lever C, to which it is attached by a link, and this lever is so constructed that when it lifts beyond a certain point it seizes and lifts the rod R, much in the same way as the lifting washer in the Brush lamp* lifts the rod of the carbon holder. S is a tension spring attached at its upper end to the top of the armature, and hooked at its lower end to the arm of the bell-crank lever L fixed in such a position that the tension of the spring S can be regulated by an adjustment screw shown in the figure. The movement of the armature therefore is controlled by the varying attractive force of the magnet M M drawing it upwards, and the adjustable tensile force of the spring S pulling it in the opposite direction; and in order to prevent a sudden and violent variation in the attractive influence of the magnet from setting the lamp "jumping," the lower end of the armature is attached by a small piston rod and piston, which moves in a little cylinder or "dash-pot" C containing glycerine, in which the piston is immersed, and the controlling action of this little contrivance can be adjusted within certain limits by allowing more or less glycerine to pass from one side of the piston to the other.

This adjustment is effected by a very simple contrivance shown in the figure. The piston of the glycerine cylinder is composed of two discs, the one fitted to the piston-rod and the other capable of being rotated through a small angle on its centre, which is coincident with that of the other disc as well as with the axis of the piston-rod. Around the edges of both discs are cut three notches at equal angular distances apart of 120 degs., and by the angular position of the movable disc with respect

ROGER'S METHOD OF SUBDIVIDING THE ELECTRIC CURRENT.

THE following description, with accompanying illustrations will sufficiently explain the system by which Mr. Rogers of St. Clement's House, Lombard-street, E.C., proposes to subdivide and subdivide the electric current for lighting purposes. We gave a brief account of an exhibition of the apparatus on p. 125, ante, and the patents now being complete, we are enabled to illustrate the devices adopted

The object of the invention is improved means and apparatus for dividing and subdividing the electric current for lighting or other purposes, by means of pairs of spherical, conical, semi-spherical, ball, or flat, waves, or other suitable-shaped metallic bodies, having clips or other appliances for the attachment of the primary wires from a dynamo machine or other electric force producer, and with a series of other clips or other bands, loops, or edges of the metallic bodies, to which other wires can be connected for conducting the fluid to any desired number of lamps or carbons, or to other shaped vessels or metallic bodies arranged in pairs, from which again wires can be conducted to other lamps or carbons. The sizes of the ball or other shaped vessels or cups, if of ball shape, is generally of greater thickness than the body for accumulating and governing the fluid. The bands are also of greater thickness than the body for a similar purpose. Should the vessel have a spherical or globular form, the clips above referred to may be fixed upon a central band or ring, and instead of the single clips being on the apex, it may be fixed to the collar or stem on which the globe stands. For intensifying light, the series of clips on the bands for the vessels may have the primary wires of several electric force-producers attached to them, so that the united current may be transmitted through the apex wire of the ball-shaped vessel, or through the collar wire of the spherical vessel to one or more lamps or carbons. Any number of these metallic bodies may be used, between the force-producer and the light or lights if desired, for intensifying on the one hand, or dividing on the other.

Fig. 1 is a section of a bell-shaped apparatus, A, with lining vessels in the interior for current intensifying and distributing purposes; B is the apex, with a conducting wire, C, attached by the screw clip D, and E is the band or base around which a series of other conducting wires, F, are looped, leading to and connected with electric lamps for producing light from one main dynamo or other force-producer, as before mentioned, or for distribution of current for other purposes.

Figs. 2 and 3 are section and plan of a branched disc, with a wire arranged at the centre and branches for other wires. Many different forms can be used, but it is unnecessary to illustrate them.

The several branch conducting wires attached to the base or rim of any of the intermediate accumulators of current force or fluid may be led and attached to other gathering or accumulating apparatus, the subdividing being effected by pairs of intermediate apparatus of smaller sizes than those of the main pair, A further subdivision of the current may be effected by the attachment of the subsidiary wires to the second pair of apparatus which may be like the other or of different forms, and the distribution and redistribution may be carried out until the current is, so to speak, absorbed, or almost absorbed, by the several apparatus into which it passes.

Fig. 4 represents one of a pair of current accumulating apparatus, A, within a box, H. To the sides of this apparatus A one of the subdividing wires of the dynamo or battery is attached. The branch or subsidiary wires leading from the rim of the apparatus, nine in number, pass through a partition, J, of the box to the sides of nine other, but smaller, apparatus attached, and the box in which it is arranged is provided with nine smaller apparatus with branch or subsidiary wires from the rim of the primary one to their centres, in a similar manner and for the same purpose as that described for the completion of the circuit.

THE LACHAUSSÉE ELECTRIC MACHINE AT THE PARIS EXHIBITION.

In our preliminary general notices of the electric lighting apparatus at the Exposition d'Electricité, we gave a general outline of the characteristic features of the very interesting electric generator of M. Lachaussée, of Liège, which, together with the Soleil installation, forms the picture gallery and in the Belgian Section, constitute the highly important exhibit of the Compagnie Générale Belge de Lumière Electrique of Brussels. In the present notice we give illustrations of the Lachaussée apparatus, and as some of the peculiarities of our present issue we describe the Soleil system of electric lighting to which we also referred in the same preliminary notice.

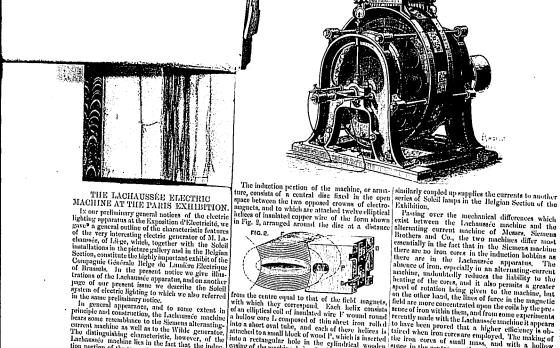
The general appearance, and to some extent the principle and construction, the Lachaussée machine bears some resemblance to the Siemens alternating-current machine as well as to the Wilde generator. The distinguishing characteristic, however, of the Lachaussée machine lies in the fact that the inductive portion of the apparatus or "armature" is fixed while the field magnets are rotated, a form of construction possessing several features of convenience to which we shall refer further on, and which it shares with the Jablochkoff, alternating Gramme, and Gerard machines, the latter of which it somewhat resembles from any other.

The rotating magnetic field is produced by two sets of electro-magnets, each set consisting of a crown of twelve electro-magnets, and attached to the shaft in such a position that the free ends of the one set are directed towards the free ends of the other set, but separated by a space within which is fixed the armature. The coils of these field magnets are connected together in series, in such a way that the direct current from a small Gramme machine in exciting the series given to the magnets, polarities alternating in direction around each crown, and of the same time produces opposite polarities in the

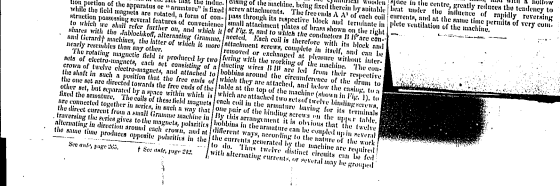
See end, page 505.

† See end, page 482.

corresponding magnets in the two crowns which are presented towards one another. These two sets of magnets are mounted on two discs of iron, which are keyed on to the driving shaft of the machine, and are rotated with it in the usual way by a belt driven from the engine. The current from the exciting machine is conducted to the rotating magnets (one set of which is shown in the illustration, Fig. 1), through a pair of metallic brushes pressing against cylindrical contact pieces forming part of the driving shaft, but at the same time being insulated from it. The position of these brushes is shown to the left of Fig. 1.



The induction portion of the machine, or armature, consists of a central disc fixed in the open space between the two opposed crowns of electro-magnets, and to which are attached twelve elliptical bobbins of insulated copper wire of the form shown in Fig. 2, arranged around the disc at a distance



from the centre equal to that of the field magnets, with which they correspond. Each bobbin consists of an elliptical coil of insulated wire F wound round a hollow core composed of thin sheet iron rolled into a short oval tube, and each of these bobbins is attached to a small block of wood F, which is inserted into a rectangular hole in the elliptical wooden ring of the machine, being fixed thereto by suitable screw attachments. The free ends A A' of each coil pass through its respective block and terminate in small attachment plates of brass shown on the right of Fig. 2, and to which the conductors H H' are connected. Each coil is therefore wire wound, but the core is of iron, and can be removed or exchanged as circumstances may require, without interfering with the working of the machine. The conducting wires H H' are led from their respective bobbins around the circumference of the drum to which they are attached, and below the casing, to a table at the top of the machine (shown in Fig. 1), to which are attached two mixed twelve binding-screws, each coil in the armature having for its terminals one pair of the binding screws on the upper table. By this arrangement it is obvious that the twelve bobbins in the armature can be coupled up in several different ways, according to the nature of the work to be done. The twelve distinct circuits can be fed with alternating currents, or several may be grouped similarly coupled up supplies the currents to another series of Soleil lamps in the Belgian Section of the Exhibition.

Passing over the mechanical differences which exist between the Lachaussée machine and the alternating current machine of Messrs. Siemens Brothers and Co., the two machines differ most essentially in the fact that in the Siemens machine there are no iron cores in the induction bobbins as there are in the Lachaussée apparatus. The absence of iron, especially in an alternating-current machine, undoubtedly reduces the liability to the heating of the coils, and it also permits a greater speed of rotation being given to the machine, but on the other hand, the loss of force in the magnetic field are more concentrated on the coils by the presence of iron within them, and from some experiments recently made with the Lachaussée machine it appears to have been proved that a higher efficiency is obtained when iron cores are employed. The making of the iron cores of small mass, and with a hollow core in the centre, greatly reduces the tendency to heat under the influence of rapidly reversing currents, and at the same time permits of very complete ventilation of the machine.

together so as to combine the currents from two or more bobbins, so as to form one larger current. In this case alternate bobbins are connected together in series, and if the intermediate bobbins are added, their corresponding binding-screws on the table are so connected to those of the first set, that all the currents transmitted into the circuit are in the same direction.

With one of these machines working in the nave of the Exhibition, six of the Soleil lamps in the picture gallery are worked in series, each having an arc of 20 millimetres, absorbing for that installation about 24 horse power. And a smaller machine

The Weston machine for running incandescent lamps is of the same general construction as the other Weston machines already described, but differs in many of its details, and is, in one respect at least, entirely new.

Incandescent lamps being used in multiple arc instead of in series, it is necessary that the electromotive force of the machine should be kept constant, and that the quantity should vary directly as the number of lights in circuit.

It is obvious that with a generator of constant electromotive force the current is absolutely proportional to

$$\text{for since } Q = \frac{E}{R} \text{ if } E \text{ be constant, } Q \text{ will vary inversely}$$

as R; but in the multiple-arc system of distribution, the resistance of the conductors is practically zero, and R is directly and accurately, with E constant, Q varies directly as the number of lamps, assuming of course that the lamps are uniform.

In all machines any variation in the external resistance acts upon the quantity of the current generated, but in all other machines with which we are familiar, the electromotive force of the current appears to be largely affected by variations in the quantity, so that any considerable change in the number of lights in circuit materially changes the current passing through the remaining lamps, and makes a readjustment of the latter necessary. Regulators of various kinds have been used to overcome this difficulty by varying the strength of the field to compensate for changes in the number of lamps in circuit. Such devices, whether manual or automatic, are open to the objection that they require attention of some kind, and cannot be relied upon in all cases to act quickly enough to save the lamps.

Mr. Weston has succeeded in constructing a machine of which the electromotive force is constant, and practically independent of the quantity of the current, and the most violent fluctuations in quantity seem to exert no appreciable influence upon the electromotive force. As for instance, with the hundred-light machine, ninety-nine lights may be turned off suddenly, and instantly without endangering the remaining lamps by heavy-duty affecting the brilliancy. This is no mere theoretical result, but is of importance for the incandescent system now being over-estimated. We are obliged, however, from lack of space, to defer a description of the particular construction of this machine for the present.

The Weston machine very desirable to have some device for varying the electromotive force of the machine within certain limits. For example, in the case of incandescent lamps it is seldom that the speed of the armature remains exactly that required to give the precise electromotive force to bring the lamps up to the standard illuminating power. It is also nearly impossible to make the incandescent lamps of perfectly uniform resistance, and the necessitates a change in the electromotive force to suit the lamps in circuit. Sometimes, also, it is desirable to have in which the illuminating power of the lamps must be varied as a whole. This is done by the use of a resistance-coil of German silver wire, which the light is put in circuit by all times.

In the arc system it is absolutely necessary that the electromotive force of the machine shall admit of wide variations, since this is the only available means of adjusting the machine to a varying number of lights, the resistance of the conductors remaining the same. This is constant, as is supposed, and if variations of the lamps are to be kept within practicable limits. The Weston machine is designed to meet these requirements.

It consists of the chestnut, which is shown in Fig. 36 interposed in the field circuit. The coils of the machine in four are connected with the terminals of resistance coils of German silver wire contained in the box. The resistance of the field circuit, and consequently the strength of the current, may be varied at will by turning the handle of the chestnut, so as to adjust the machine for running any number of lights from one to its full complement. This action of the chestnut does not at all disturb the proper operation of the machine, as is the case where the resistance is varied in the carbon arc, a field partially shunted out of the circuit. The twenty-four brass buttons on the chestnut with one long contact with the full complement. The same form of chestnut is used for the adjustment of the incandescent lamps, and for this purpose we have added the rheostat, which is divided to vary the illuminating power of all the lights, it is not used after the first adjustment is made.

A striking peculiarity of the Weston arc system is the shortness of the arc used. The arc is usually about one-tenth less than .02 of an inch in length. The arc in the Brush and most other systems, is .08 of an inch. In the Weston system a current of about 10 volts is used, while in the Brush machine a current of 50 volts is used, the Weston arc requiring only one-fifth of the energy. The short arc system is the incensed size of the fine coal-dust necessary for conveying the increased quantity of current without too great loss; but this disadvantage is more than counterbalanced by the steadiness of the light. More light is obtained for a given expenditure of current with a short arc than with a long one, other conditions being equal. Where a long arc is used there is a marked phosphorescence of the rays at the violet end of the spectrum, giving the light a bluish tinge. The intensity of the light is greater. With a short arc the light approaches more nearly a pure white, and is much more actinic and agreeable to the eye. It is also more diffusive—that is, it produces more perfect illumination at a distance from the lamp. The arc is also much steadier, and the impurities in the carbon, which usually produce disturbance with a long arc, do not appear to affect the short arc.

But by far the greatest advantage of the short arc system is the largely decreased liability of injury to persons coming in contact with the conductors. We have no doubt that the danger to be apprehended from electric lighting apparatus, as at present constructed, having been largely over-estimated; and such dangers as really exist can be overcome by proper care in the use of the apparatus. Experience has demonstrated, it is secure, that fatal accidents are possible with many of the arc lighting systems. Where currents of very high electromotive force are used, the most extreme care is necessary for avoiding accidents, and it is desirable, on this account, that the electromotive force should be kept as low as possible. It seems, on the whole, that the low electromotive force of the Weston system is a very important feature in the same circuit. The resistance of the lamps is such with a current of practically low-force potential, and the only resistance of any importance is that of the conductors. Among the many advantages of the Weston system, we have not referred to the fact that the apparatus, upon which have been attentions and the Weston machine, and we are informed that no accidents whatever have in fact occurred with this system. Probably this is to be largely attributable to the low electromotive force of the current used, but it is also due, in some degree also to the continuous character of the current. Alternating currents are known to be especially dangerous, and the substitution of a continuous current for an alternating current or an intermittent current, has been used in all cases where accidents have occurred. To whatever cause the immunity of the Weston system from accident is due, it is a matter of considerable importance to the public and is worthy of careful consideration.

Different forms of Weston arc lamps are used. Fig. 31 is a simple form of double-carbon lamp.

The feeding mechanism of the duplex lamp is shown in Figs. 32, 33, and 34. In this there is but one clutch employed. It is for controlling the feeding of both sets of carbons. The upper carbon is supported with two sets of nuts, one of coarse pitch, belonging to the feed of the arc circuit, and the other of fine wire for carrying the shunt. The negative fact that an alternating current or an intermittent current, has been used in all cases where accidents have occurred. To whatever cause the immunity of the Weston system from accident is due, it is a matter of considerable importance to the public and is worthy of careful consideration.

Different forms of Weston arc lamps are used. Fig. 31 is a simple form of double-carbon lamp.

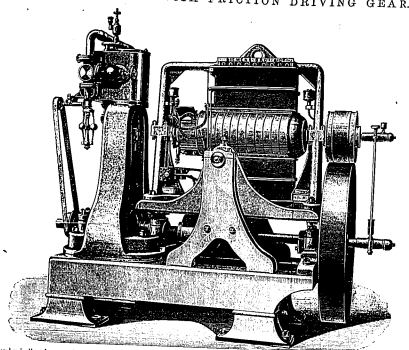
The lower terminal of the coarse wire helix is electrically connected with the upper carbon carrier, and the current and the feeding mechanism are slotted sliding-contact

SIEMENS' DYNAMO WITH FRICTION DRIVING GEAR.



Considered mechanically a dynamo-electric machine is an exceedingly simple appliance, and one which at first sight would appear to present no difficulties in driving. It is true that as usually run at a high speed, but quick-running machines are so rarity, and the best means of transmission to draw upon in days when each generator fed but one lamp, and consisted from two to four horse-power only, the matter was simple enough, but as the number of lamps supplied from one source increased, the subject developed a new difficulty and less familiar shape. Belts had now to be made wider and driving pulleys larger, while countershafts had to be driven at higher speed, and furnished with pulleys of unusual diameter. As the incandescence lamp gained ground another stage was reached, for whereas with arc lamps the maximum power absorbed by one generator seldom exceeded 20 horse-power, now it often reaches as much as 40 or 50 exceptionally double that, and at an electric light exhibition the bewildered visitor has a difficulty in finding the dynamos among the concourse of belts, engines, pulleys, and belts which entirely overshadow them. So long as there is ample space at disposal there is no great objection to be made to this; machines running at 600 or 700 revolutions per minute cannot well be driven directly, and belts are probably the best, certainly the best understood, means of transmitting the power to them. But unfortunately the requisite space is not always to be had; electric lighting is usually regarded as an adjunct which might be stowed away in a corner, generally in a vault or a most unsuitable, where it is impossible to employ a belt of sufficient length to run well, and then follow the mistakes which have so often brought discredit upon the new illuminant.

But however arrangements may be as the space allotted to the electrician on hand, it is always much larger than that within which he is confined when he undertakes the lighting of an ocean steamship. In a corner partitioned off from a coal bunker, he is expected to erect duplicate engines and plant for 500 incandescence lamps, and he often finds the problem very difficult of solution. He has to provide accommodation for two engines each capable of indicating 60 or 70 horse-power, and for two dynamos, while each engine must be so arranged that it will drive either generator, so that the chances of a breakdown may be reduced to the smallest amount. Arguing from the advantages offered by the electric light engineers to shipowners it would be reasonable to expect that they should have a fairer chance of doing themselves justice, but the question of space can be settled on theoretical grounds; the exigencies of trade demand that the machinery shall be contained within the smallest possible compass, and it is expected that the ingenuity of engineers will find a means of fulfilling this condition.

In our issue of May 4 we illustrated and described a method of rope transmission for driving dynamos machines on board ship, devised by Mr. J. S. Haworth, of Manchester. At the date of our article he had already applied it, on behalf of Messrs. Siemens Brothers, in twenty-three instances, of which the first was on board the City of Rome; since that time the number has been further increased, and in every case the ropes have given perfect satisfaction, showing no tendency to slip, and requiring but little supervision. The growing use of marine installations is now, however, surrounding upon the small area required even for the rope transmission, and Mr. Haworth has introduced a new method of driving, which we illustrate above, by which will, we think, from its novelty and simplicity, interest many of our readers besides those professionally connected with electric lighting. The system is that of friction or rolling contact, is of course perfectly well known, but hitherto it has never been applied to driving electric generators, nor, as we think, for transmitting so much as 40 horse-power. The difficulty in the application lay in the necessity of avoiding a great strain upon the bearings of the dynamo. The armature runs so closely to the field magnets that any considerable wear in the bearings brings about the destruction of the former, and since the contact between the rolling surfaces is theoretically only a line, it was feared that there must be a heavy pressure brought to bear upon them to gain the required adhesion, and that it would be dangerous to transmit it through the bearings. To avoid this the generator is mounted on a cradle carried in trunnions, so that it is perfectly free to swing in a vertical plane fore and aft, and so accommodate itself to any position of the driving pulley, the stress in the bearings being only that due to the weight of the armature, and the turning moment required to drive it, far less than that to which it is subjected when driven by a belt or by a rope.

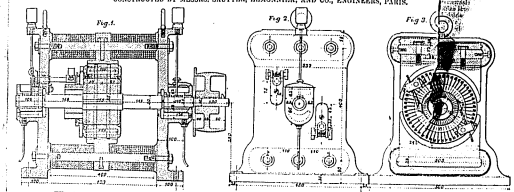
The pulley on the armature spindle is composed of discs of paper powerfully compressed between two gun-metal face-plates, and turned to a smooth cylindrical surface. It runs in contact with a large cast-iron pulley, which is also the flywheel of the engine, and the two are maintained in intimate connexion by a pair of tightening screws. The armature spindle and the flywheel shaft are each turned down at the end and run as gun-metal journals provided with steps or bags for the passage of these bars. At the lower end, each bar has a head, and at the upper end it is screwed to receive a nulled head nut, with a head 2 in. in diameter. Under each nut is a short helical spring about 1 in. in length, so that as the nuts are screwed down the strain is gradually increased, and a matter of fact the pressure required to keep the two rolling surfaces in working contact is exceedingly slight, two or three turns of the nuts, made only by the thumb and finger without any lever or screw-key, being amply sufficient for the purpose. The engraving represents a Siemens S D, dynamo, designed to feed 200 8-candle lamps and a 6 horse-power Tangye engine, controlled by a Pickering governor.

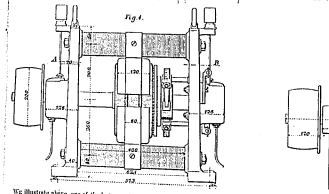
The first machines driven in this manner fed 60 lamps, and were placed on board the s.s. Jurmala, in which they have answered admirably. There is now a similar one upon the City of Chicago and two upon the Manitoba, of the Allan and Oriental service, and gradually increasing sizes, up to the largest constructed by Messrs. Siemens Brothers, are now being adopted to this method of driving with very successful results. When duplicate dynamos are installed, a pair of engines are placed in the centre of the hull with a generator at each side. The engines are not usually coupled together, but should one engine and the opposite dynamo both fail, then the two crankshafts can be coupled together to transmit the power from the remaining engine to the other generator. Our engraving represents one of five apparatus exhibited before the British Association at Southport.

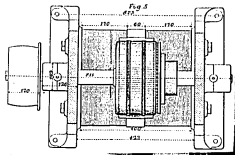
Canalisation of the Isthmus of Corinth.—The works here are advancing rapidly, and will be completed in four years. The quarrying of the rock has not proved as difficult as was anticipated. The total quantity of soil to be removed is estimated at about 1,500,000 cubic yards.

THE GRAMME DYNAMO-ELECTRIC GENERATOR FOR FIVE LIGHTS.

CONSTRUCTED BY MESSRS. SAUTTER, LEMONNIER, AND CO., ENGINEERS, PARIS.







We illustrate above one of the last new types of the Gramme dynamo-electric generator adopted for feeding five arc lights. Several examples of this machine were shown at the late Paris Electrical Exhibition, her two, five, six, and twenty lights, and which were employed for lighting in the main and third avenues on the first floor. These generators were exhibited by the Gramme Company, by M.M. Sautter, Lemonnier, and Co., and by the Spanish Electrical Company. The machine consists of a ring-core electro-magnets, in the centre of each of which a bearing is formed for the driving shaft on which the ring is mounted, near the top and bottom of each frame a face is formed with a transverse groove formed in it (Fig. 1) for the reception of the cores of the electro-magnets. The shape of the cores is shown in Figs. 1 and 2; they are flat rectangular bars 11.20 in. long by 1.26 in. thick. These cores, besides resting on the grooves formed in the frame, are secured by bolts passing through, three at each end of the core (Fig. 2). The cores are coiled around indicated on the drawings. In the middle of each magnet is this projection, 4.72 in. thick and held by screws to the core (Fig. 3); they are rather wider than the ring (7.122 in.) and the inner faces are semicircular, so as to embrace almost its complete circumference, a small space only carrying the revolving armature. A projection at one end beyond the frame is formed for driving pulley, 7.87 in. in diameter; the size of the steel shaft is 2.17 in. in diameter; the size of the ring, which is wound on a wooden core, 5.91 in. wide and of such a diameter as to fit tightly within the The outside diameter of the finished ring is 20.24 in.; the pole-pieces, and it will also be seen that the ring is strengthened by the addition of two bands or hoops, mounted on the wooden core by means of a copper ring, through which screws are passed at intervals into the core. Between the metal bands of the collector, on which the brushes bear, and the central shaft, a metal sleeve is interposed, as shown in the section. The detailed arrangement of the collector is indicated in Fig. 3. The brushes are controlled by an endless screw operated from the outside of the frame, so that their position may be regulated to secure the best effect. The great simplicity and excellent design of this machine give it quite a special character, and amongst the novel details may be indicated that of forming the bearings in the frames and the mode of lubricating, which is clearly shown in Fig. 1. It will be noticed that the bearings are of unusual length, 4.32 in., to enable the machine to run at a high speed with perfect steadiness. The following are some of the leading features of this generator:

Total length including pulley	...	...	52.09 in.
Width	...	...	21.26 "
Height	...	...	21.26 "
" of shaft above base	...	...	11.02 "
Diameter of pulley	...	...	7.87 "
Face of pulley	...	...	3.94 "
Total weight	...	...	792 lb.
Resistance of ring	...	...	0.0213 ohm.
Weight of wire on ring	...	...	1.5 ohms.
Resistance of electro-magnets	...	...	24.2 lb.
Weight of wire of electro-magnets	...	...	1.6 ohms.
Outside diameter of ring	...	...	1.6 lb.
Width of ring	...	...	20.24 in.
			5.91 "

This machine can be used for feeding from one to five lights by varying the speed at which it is driven and the resistance of the conductors. The annexed Table shows the most suitable speeds and resistances, as well as the space between the carbons during work and the length of arc at the point of extinction.

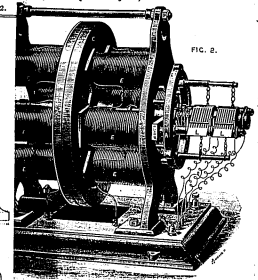
Number of lights.	Resistance per lamp.	Resistance in ohms of Conductors.	Normal lights.	Length of Arc at Point of Extinction.
1	500	1.00	1100	1.00
2	500	2.00	25	1.00
3	667	2.00	25	.87
4	1125	4.50	25	.75
5	1200	4.50	25	.63

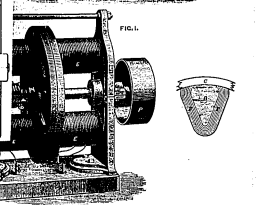
We may add that we have reproduced the illustration of this machine from our contemporary, *La Revue Industrielle*.

THE ARAGO DYNAMO-ELECTRIC GENERATOR.

(For Description see Page 62.)

JAN. 20, 1882.



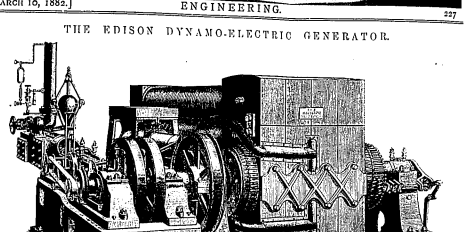


THE ARAGO DYNAMO-ELECTRIC GENERATOR.

Among the numerous dynamo-electric generators shown at the recent Paris Electrical Exhibition, were two machines of American origin, which, under the name of the "Arago disc dynamo," were exhibited by the Van House Mills Company, of Hoosac, New York. On the preceding page we publish drawings of both these machines, which we have already referred to (see ENGINEERING, vol. xxxii., p. 217). Fig. 1 shows the simpler of the two generators. It comprises, as will be seen, two pairs of electro-magnets E S, each having one end attached to the frame of the machine, and the other ends opposite each other; these magnets are so wound that they present alternate polarities, and the polarity of each pair of magnets facing one another is of an opposite nature. The magnets are provided, as shown, with sectional shaped pole-pieces, which collectively form the greater part of a disc. Each pair of magnets having such pole-pieces opposite to one another, it will be seen that at their nearest approach the edges of the pole-pieces are distant from one another by a narrow parallel space. Within the magnetic field thus formed revolves a wheel or disc, in which are mounted a series of six sector-shaped bobbins. These are clearly shown in Fig. 3, where B is a wooden core, F the coil, and C the zinc of the disc. All six of these coils are wound in one direction, but are coupled up in such a way that a current passing through them in series, would circulate round the disc in alternate directions. The coils are held in position by two plates on the driving shaft, and by the double copper ring G, that forms the periphery of the wheel.

The second and larger machine is shown in Fig. 2. It is constructed on the same principle, but involves more complication. In this generator there are six pairs of electro-magnets, arranged as in the smaller machine, and furnishing six alternating magnetic fields. The reversing disc is also as already described, only it has eight coils with wooden cores. The commutator consists of 24 plates. The means employed for rendering the current continuous is the same in principle as that used in the Heffner Altaneck machine. The space contained

THE EDISON DYNAMO-ELECTRIC GENERATOR.



pled between two coils of the shaft connected to three plates of the commutator in such a way that the latter form three groups of eight plates each. The two brushes are always in contact with two plates corresponding to the line that divides the induction coils in two equal parts traversed by opposite currents. The commutator is mounted on the same axis as the armature and similar to the smaller commutator each of the coils of the armature is in two parts. The induced current set up in the main important of these parts produces a current that it throws into the circuit of exterior work. The induction produced in the other portion creates a current that excites the electro-magnets. On account of this arrangement the collector is divided into two distinct parts, each corresponding to one of the circuits just mentioned. The brushes L L are mounted in a special way; they supports are fixed on a ring A (upon the frame of the machine, and the brushes themselves are also carried by springs fixed to the ring. From the foregoing description it will be seen that the lamps dim dynamo is a self-exciting generator, the arrangement adopted involving the use of two sets of brushes and two commutators, one connecting the magnets with the exciting coils, and the other connecting the induction coils and the outer circuit. The frame on which the brushes are mounted can be turned round through a considerable angle, so as to adjust the brushes to the position of highest efficiency. It is stated that the large of these machines, driven at a speed of 1000 revolutions, can feed eight arc lights of average intensity, consuming about six horse power, but accurate data as to its capacity are wanting. We are indebted to our contemporary *La Lumière Electrique* for the illustrations of these generators, and partially for the description of them.

THE EDISON SYSTEM OF ELECTRIC ILLUMINATION.

We have from time to time, in the pages of this Journal, referred to the many interesting and ingenious devices introduced by Mr. Edison in connection with electric illumination, and which have gone to develop what is probably the most complete and well-elaborated system of incandescent electric lighting which hears his name, and which formed one of the most attractive exhibits at the Exhibition of Electricity at Paris, as it does at the present electrical display at the Crystal Palace. At a future time, however, the public will have an opportunity of seeing in practical and extensive operation, as ordinary purposes by the lighting of the street lamps, and most of the shops and warehouses, throughout the whole length of the Holborn Viaduct in London, including part of the General Post Office, and the whole of the City Branch, for this installation is in a very forward state, and is rapidly approaching completion.

In our issue of the 21st of October of last year* we illustrated and described the great Edison dynamo-electric generator which was used during the progress of the Paris Exhibition, but which after the close of the work, illuminating as it did nearly a thousand Edison-Swan lamps formed an attractive a feature of that successful exhibition. In the present notice we propose to describe another enormous machine, generator of improved construction, two of which have recently been brought over from New York, and erected at the offices of the Edison Electric Light Company on the Holborn Viaduct, for the working of the installation above referred to. In this installation there will be no less than a thousand full size, or sixteen-candle incandescence electric lamps maintained constantly in operation and which are distributed as according to the list given in the next column. All these lamps will derive their current from one of the two machines which are fixed in the basement of the company's offices, the other machine, which is very similar, being kept in reserve in the event of any accident occurring to the working

* See ENGINEERING, vol. xxxii., page 467.

machine, as well as to take its place during periods of repairs.

The illustration on the opposite page is a general view of one of these interesting machines, which consists of an enormous dynamo-electric generator, similar in general design to the great machine at the Paris Exhibition, but differing in several important details of construction, particularly side by side upon the same bedplate and foundation with a horizontal high-pressure Porter engine of 130 horse power, the main shaft of which is a prolongation of the axis of the armature of the generator.

Upon referring to the illustration it will be seen that this generator is of the Edison horizontal type, the magnetic field being produced by a battery of twelve horizontal electro-magnets disposed in three rows of four magnets each, two rows being attached by their ends to the upper pole-piece, and one row to the lower pole-piece, the further ends of all being united by a massive bed plate, seen at the back of the figure. The armature is driven at a speed of 350 revolutions per minute, within a cylindrical space bored out of the very massive pole-piece shown in the front of the illustration, and which are built up of twelve heavy blocks of cast iron held together by long bolts threaded through them, and by surface coupling plates screwed on to three of their faces. The armature, like that of the Paris machine, is of cylindrical form, and is composed first of a core built up of no less than 2200 discs of very thin sheet iron, alternating with discs of tissue paper, while at every foot measured in the direction of its length, it is disc of thick iron to give stability and rigidity to the armature; the whole is squeezed and bolted together by eight longitudinal bolts passing through all the discs, and through a pair of end plates by which the pressure is applied, and the whole is locked with a tube of wood, so as to insulate the armature core from the rest of the machine. The induction portion of the armature is composed of 105 straight longitudinal thick bars of nearly pure copper of trapezoidal cross-section, arranged at equal distances around the core and insulated from it. These 105 copper bars are united at alternate ends to as many copper discs, half of which on one side are strong on to the shaft at one end of the armature and the other half at the other; all the discs are insulated from the shaft and from one another, and the bars are so connected with them that the bars and discs together form a continuous and closed circuit, wound as it were longitudinally around the core. This coupling up is effected as follows: each of the copper bars is connected at each end to the copper disc at that end, and the diametrically opposite edge of the same disc is connected to the corresponding bar at the opposite side of the armature; this bar in its turn is connected to the disc at the other end, and the opposite edge of this disc is connected to the bar next in rotation to the bar we started with, this again to the next disc at the other end, until all the bars and all the discs have been connected together in such a way that a current of electricity transmitted through the armature would pass along one bar, across the disc at one end, back by the next bar, across the disc at the opposite side, then across a to No. 2 disc and back on the opposite side to another disc, so that for all electrical purposes the making up a thick copper coil of extremely low resistance, wound longitudinally over an iron cylinder in a single layer, the various convolutions of which belong at equal angular distances apart around the circumference of the cylinder.

In the disposition of the inductive portion of the armature it is identical with the armature of the ordinary Siemens direct-current machine, but the coupling up is simpler, and the course taken by the currents produced is in consequence somewhat different.

The diameter of the armature when complete is 25 in., its length is 5 ft., and its weight is over four tons. When it is remembered that this mass is revolved within the hollow cylindrical space between the pole-pieces at a speed of 350 revolutions per minute, it will readily be anticipated that if the heavy bars of copper were attached to the armature only at their ends, which are between 4 ft. and 5 ft. apart, and revolving as they do at a circumferential speed of 43 ft. per second, the armature would be speedily destroyed by the bars flying out under the influence of centrifugal force, and coming in contact with the iron pole-pieces which embrace them. To prevent this, the bars are held together at short distances along the length of the armature by coils of steel piano-forte wire bound tightly round the bars over bands of mica, by which they are insulated from them, and some idea may be formed of the high class workmanship and fitting together of this finely constructed machine when we state that although the diameter of the revolving armature is 25 in., that of the cylindrical space within which it revolves is only 26 in., thus allowing but one-eighth of an inch clearance between the induction bars and the pole piece. It is needless, of course, to point out that this accuracy of construction adds very considerably to the efficiency of the machine, by enabling the armature to revolve in a most intense magnetic field than if, through less accurate workmanship, the magnetic poles, to insure the safety of the machine, had to be farther off.

The electro-magnets by which the magnetic field is produced, consist of twelve horizontal cylindrical bars of iron about 5 ft. long, and coiled throughout their whole length with thick insulated copper wire. The coils of three magnets are connected together in two parallel circuits of six coils each, and the resistance of the circuit so arranged, and which form a derived or shunt circuit to that of the machine, is 2 ohms. The resistance of the armature, as will be apparent from a consideration of its construction is practically inconsiderable, measuring only about $\frac{1}{1000}$ of an ohm (.00910 ohm).

The commutator is a cylinder built up of a number of insulated copper sections as in that of the Siemens and Gramme machines, there being as many copper segments as there are induction bars on the armature, and are connected to them by so many radial copper rods attached in such a manner that owing to a slight elasticity at the junction there is no tendency for them to be sheared off in the starting and stopping of the machine, a defect which showed itself in the machines of this type which were first constructed. Upon the cylindrical surface of this commutator are pressed two sets of metallic brushes or collectors mounted in spring fittings attached to a rocking arm—shown in the extreme right of the illustration—by which the angular position of the points at which the brushes make contact with the commutator can be adjusted with respect to the neutral plane of the magnetic field so as to obtain the maximum efficiency of the machine.

The motive power is a horizontal engine at the Porter type, of 130 horse power nominal, fitted with a Porter governor and expansion gear, and with a steam pressure of 120 lb.; it drives the armature which is mounted on the crankshaft at a velocity of 350 revolutions per minute, the steam being supplied by one of Messrs. Babcock and Wilcox's compound tubular boilers. The weight of the machine with its engine and bedplate, which are fixed together, is over 20 tons.

In order to keep the armature cool, thereby protecting its insulation and keeping down its resistance, there is a small blowing fan driven by the engine, and from this blower three pipes are led which communicate with three air channels cast through the pole-pieces, so as to maintain three jets of air constantly playing on the ends of the exterior armature, which, escaping right and left are, during the working of the machine, continually lashing the induction bars with air. The efficiency of this arrangement is proved by the fact that although a perceptibly warm air are, when the apparatus is in action, continually issuing from the two ends of the hollow cylindrical space within which the armature is rotating.

The Edison incandescence lamps, which will be worked on the Holborn installation, possess the general features common to the incandescence lamps of all the systems at present in use, that is to say, they consist of a fine filament of carbon enclosed in an exhausted glass envelope and rendered incandescent by the passage through it of a current of electricity of sufficient strength. We need not refer to all the distinguishing characteristics of this interesting lamp in the present notice, because we intend on an early occasion to give a detailed description of it as well as the method of its manufacture. It is sufficient for our present purpose to point out that the features which distinguish the Edison lamp from those of Mr. Swan and others in lamps, every branch and which distinguish the the material of which the carbon filament is made, and the arrangements by which it is placed in circuit with the source of electricity or generator. The incandescent filament in Mr. Edison's lamp is made of carbonised bamboo fibre, while that of Mr. Swan is of cotton carbonised by a special process, these differing again from the filaments in the Maxim and Lane Fox lamps, the former of which is prepared from paper coated in a residual vapour of gasoline, while the latter consists of carbonised vegetable fibre prepared in a very similar process. The fitting of the Edison lamp is exceedingly simple and efficient, consisting of a screw and a hole or screw forming the terminals of the carbon filament, but otherwise insulated from one another by platinoid-paris, and this little device, which is attached to the stem of the lamp, screws into a corresponding and similarly put together socket consisting of a hollow brass cone and a hollow screw, which are respectively in electric communication with the conductors leading from the generator. When the fitting of a lamp is screwed into this socket the cone on the lamp is, by the action of the screw, drawn firmly into its conical seat, and thus good metallic contact is insured not only between the two parts of this size between the corresponding threads of the two screws, and thus the resistance of the joint reduced to a minimum, and it becomes almost impossible for any of the current to be lost by faulty connection.

The conductors employed on the Holborn installation are similar in construction to those exhibited in Paris, and consist of a pair of copper rods of segments cross-section enclosed in wood gun tubing, the intervening and surrounding space being filled with a bituminous insulating composition. These double conductors or electrici mains are made in a number of sizes, the cross-section of the copper bars, and therefore the diameter of the covering tubing, being proportioned to the amount of electricity to transmit. They are laid along the subway of the Viaduct, branches—the details of which we shall describe in another notice—being taken off at places along their length corresponding to groups of desired circuits or to the various houses to which the current is supplied, and the branch conductors employed for this purpose being similar to in construction, but smaller in size, than the great supply mains with which they are connected.

In order to reduce to a minimum the occurrences of fire through the under heating, through any cause, of conductors, as well as for the protection of the

derived circuit throughout the whole system is fitted, at the point where it joins its corresponding superior main, with a safety guard or cut-off, consisting of a short length of fuse wire or other easily fusible conductor through which the derived current entering the branch from the main is transmitted, and which as long as the strength of the current is not abnormally great, transmits it, as does any other portion of the branch. The moment, however, that from any cause the current becomes strong enough to do damage, the lead wire is fused by it, and the portion of the branch which would otherwise be liable to injury is cut out of the circuit without in any way interfering with the rest of the main circuits or their branches.

Forming an important part of the Edison system are the arrangements for the regulation of the strength of the current to the work it is required to do at any one moment, and this is performed for a whole district entirely in one room at the central station. We shall describe this very characteristic and well-developed feature of the system later on, but we may briefly say that the current passing out of the central station is controlled by a regulator which by varying the resistance of the circuit of the field magnets of the machine, regulates the intensity of the magnetic field and thus weakens or strengthens the current induced in the armature, with a proportionately decreased or increased expenditure of motive power and therefore of consumption of fuel. In the regulating room is an electro-motive-force-indicator consisting of a balanced reflecting galvanometer making its indications by the movement of a spot of light upon a divided scale and showing instantly to the assistant in charge any variation of strength of current produced throughout the whole system by the turning on or extinguishing of any series of lamps. A supplementary indicator is also given by the behaviour of a small series of "pilot lights" in the regulating room and included in the general circuit.

The electricity supplied to each consumer will be measured by a most ingenious meter (which we shall describe in a future notice), placed on his own premises, and under this system those who make use of the light will be as independent of the presence in charge of the apparatus at the central station as gas consumers are at the present moment of the employés at the gas works. They will have complete control of the lights on their premises, and can turn on or extinguish any or all of their lamps without any communication with head-quarters for the *demand* for electricity, in other words, the number of channels opened to the current at any one time is instantly indicated in the regulating room, and the *supply*, that is to say, the strength of the current, can as instantly be adjusted to it.

The arrangements of this very interesting installation have been carried out under the management of Mr. Edward Hibbert Johnson, who is the representative of Mr. Edison in this country in all matters connected with the electric light, and to whom we are indebted for much information.

Within the limits of a preliminary and introductory article, such as this is intended to be, it is impossible to do more than indicate the general features of a system consisting of so many points of interest, but we have in the present notice gone over sufficient ground to show that if the panic was premature which was produced in the gas-share market some three years ago by the announcement that Mr. Edison had discovered a complete and practical system of electric lighting to compete successfully with gas on all its points, Mr. Edison has since made good his claim to the laurels he was thought to have lost by the natural collapse of an unreasonable scare, for, if the permanent working of the installation on the Holborn Viaduct prove as successful in its results as those of the experimental trials have—and there is no reason to suppose it will not—there can be little doubt that as an investment for electric illumination greater in magnitude and importance than has ever preceded it. And we need hardly say we hope that such may prove to be the case.

THOMAS AVELING.

It is with very great regret that we record the death on Tuesday last, the 7th inst., of Mr. Thomas Aveling, the well-known senior partner of the firm of Messrs. Aveling and Porter, of Rochester. Mr. Aveling's decease took place after a very brief illness, which was not at first deemed to be serious, and the news of his death will cause a shock to a wide circle of friends. Mr. Aveling was born at Rye, in Cambridgeshire, on the 11th of September, 1824, and he was thus but little over 57 years of age at the time of his decease. His family was one of the oldest in Cambridgeshire, in which county it has been settled between four and five centuries. His grandfather was high sheriff for Cambridgeshire and Huntingdonshire in 1801. Mr. Aveling's father died when he was very young and his mother subsequently removed to Rochester, where she was married a second time to the Reverend John D'Urban, who for more than twenty years was in clerical charge of the parish of Hoo-Saint-Werburgh. It was in the Hundred of Hoo, and during the latter part of the above-named period, that Mr. Aveling first gained practical experience in agriculture, while later on he became a farmer at Hackinge, in the Weald of Kent.

Mr. Aveling was, however, in many ways more fitted for being an engineer than a farmer, at all events as far farming was carried on in those days, and he was impressed with the fact that a great deal remained to be done to adapt steam power thoroughly to agricultural requirements. This led him to give up farming and establish small works at Rochester for the manufacture and repair of agricultural implements. One of the points to which Mr. Aveling early devoted his attention was the rendering of agricultural engines self-moving, and in 1859 he took out a patent for an arrangement of pitch chain gearing applicable to such engines. Mr. Aveling did not at first build engines himself, but applied this gear to ordinary portables constructed by Messrs. Clayton and Shuttleworth. Later on, however, he commenced engine building on his own account, and in 1865 he exhibited the first of [illegible] engines at the Royal Agricultural Society's [illegible] at Canterbury, while in 1861 (the having been [illegible] joined by Mr. Porter) his firm, Messrs. Aveling Porter, exhibited an engine at the London national Exhibition. It is to be borne in [illegible] that Mr. Aveling's earlier engines were not [illegible] engines in the ordinary acceptation of the te [illegible] simply self-moving agricultural engines not [illegible] to haul after them a heavier load than a th [illegible] machine. Later on, however, the firm of [illegible] and Porter took up the manufacture of [illegible] engines for hauling purposes as well as [illegible] steam ploughing engines, their works a [illegible] developing in size and productive power, and [illegible] reached their present important position.

Of the numerous improvements in agricultural locomotives and traction engines introduced by Mr. Aveling, we can give but a hasty sketch here. The earlier engines the power was, as we have stated, transmitted from the second motion shaft to the driving axle by a pitch chain, and for many years Mr. Aveling was a strong advocate for this form of gear and did much to perfect its manufacture. Thus by the employment of a duplex drilling machine to insure accuracy in the pitch of the links, the use of case-hardened steel for the pins, and by the choice of good proportions, he secured for this chain gear a durability far beyond that which it possessed before he introduced his improvements. He also devised convenient arrangements for tightening the chain when stretched by moving the bearings of the second motion shaft, at the same time maintaining a constant distance between that shaft and the crankshaft, so as not to interfere with the action of the tumbler-gear. The introduction of steel castings, however, and cast steel spur, may be said to have revolutionised traction engine construction, and it led Mr. Aveling to abandon the chain gear entirely for all ordinary engines.

Mr. Aveling was a thorough believer in the benefits of steam jacketting, and upwards of twenty years ago he patented his well-known arrangement in which the cylinder is surrounded by a capacious jacket forming the steam dome, the steam traversing this jacket on its way to the valve chest, which it encircles on the top. This is an arrangement which has now become almost universally adopted by traction engine builders, and it is undoubtedly an admirable one for its purpose. It is to Mr. Aveling also that is due the general adoption of single cylinders for traction purposes. We believe that we are correct in stating that Mr. Aveling was the first to build a traction engine with a single cylinder, and for many years he had to uphold the advantages of that arrangement against great opposition. The sufficiency of the single cylinder for all ordinary conditions is now, however, generally acknowledged, while its simplicity has led to its extended adoption.

A feature connected with Mr. Aveling's earlier practice which deserves notice here, was the arrangement of steering wheel, which he devised about 1860, and which many of our readers will remember as being fitted to the engine exhibited by Messrs. Aveling and Porter in the International Exhibition of 1862. According to this plan, which was for some years adopted by the firm to the exclusion of other arrangements, the leading axle had attached to it a light frame projecting for[illegible] wards, this frame carrying at its front end the vertical axis of a forked spindle, in the fork of which was mounted a sharp-edged wheel bearing on the road. This wheel could be readily diverted by a tiller to either side, and when thus diverted, it led off to the side towards which it was pointed, taking with it the front end of the light frame and so leading round the leading axle. The engine thus followed the pilot wheel as it might be named.

During later years Mr. Aveling's attention was devoted to improvements in detail rather than to the introduction of any radical changes in traction engine construction. Amongst these improvements may be specially noticed the plan of carrying up the side plates of the firebox casing to form the brackets for the crankshaft and countershaft bearings, and in steam ploughing engines for working on the double engine system, the introduction of right and left-hand engines so as to secure that the rope when hauling should in both engines lead on to the side of the drum next the driving pinion, thus relieving the drum spindle of by far the greater part of the strain.

The combination of a traction engine and crane—an arrangement which has [illegible]

[illegible] machine, as well as to take its place during periods of repairs.

In the street lamps for the whole length Number of

[illegible] on the side of his death it may, we think, be safely said that no man living had an extensive practical knowledge of steam haulage on roads as Mr. Aveling, or as thorough an appreciation of the requirements which traction engines ought to fulfil. A firm believer in the great future of steam traction he combined with exceptional experience, keen powers of observation, and abundant energy and good common sense, which served him in good stead in overcoming failures and opposition under which most men would have given way. Of the success which attended his efforts the enormous number of traction engines now in use in Kent alone forms the best record; amongst those being the numerous military engines (adapted for either rail or road service) which he constructed for the use of the Royal Engineers at Chatham and on the perfection of which he bestowed much attention.

Another matter with which Mr. Aveling was most prominently connected was the introduction of road rolling by steam. The idea of employing steam power for this purpose originated with the late Mr. William Clark, when chief engineer to the municipality of Calcutta, and a steam road roller was designed for Mr. Clark by Mr. Batho, then of Birmingham. It was not, however, until the construction of such rollers was taken up by Messrs. Aveling and Porter, that they came into use in this country. As in the case of traction engines, so is that of steam rollers, Mr. Aveling carefully studied the requirements to be fulfilled in practical working, and he introduced successive improvements from time to time as experience showed the weak points of the earlier designs. Mr. Aveling soon appreciated the serious objections which existed to the employment of the very heavy rollers at first thought to be necessary, and he devoted himself to the perfection of machines of comparatively light weight and capable of being readily handled in any thoroughfare. A great point was that, in his traction engines, Mr. Aveling had obtained a very economical

A feature connected with Mr. Aveling's earlier practice which deserves notice here, was the arrangement of steering wheel, which he devised about 1860, and which many of our readers will remember as being fitted to the engine exhibited by Messrs. Aveling and Porter in the International Exhibition of 1862. According to this plan, which was for some years adopted by the firm to the exclusion of other arrangements, the leading axle had attached to it a light frame projecting forwards, this frame carrying at its front end the vertical axis of a forked spindle, in the fork of which was mounted a sharp-edged wheel bearing on the road. This wheel could be readily diverted by a tiller to either side, and when thus diverted, it led off to the side towards which it was pointed, taking with it the front end of the light frame and so leading round the leading axle. The engine thus followed the pilot wheel as it might be named.

During later years Mr. Aveling's attention was devoted to improvements in detail rather than to the introduction of any radical changes in traction engine construction. Amongst these improvements may be specially noticed the plan of carrying up the side plates of the firebox casing to form the brackets for the crankshaft and countershaft bearings, and in steam ploughing engines for working on the double engine system, the introduction of right and left-hand engines so as to secure that the rope when hauling should in both engines lead on to the side of the drum next the driving pinion, thus relieving the drum spindle of by far the greater part of the strain.

The combination of a traction engine and crane—an arrangement which has [illegible]

ON THE MECHANICAL PRODUCTION OF ELECTRIC CURRENTS.—No. I.

THE object of these articles is to lay down in the simplest and most intelligible way the principles which are concerned in the mechanical production of electric currents. Every one knows now that electric lights are produced from powerful currents of electricity generated in a machine containing magnets and coils of wire, and driven by a steam engine, or gas engine, or water-wheel. But of the thousands who have heard that a steam engine can thus provide us with electric currents, how many are there who comprehend the action of the generator or dynamo-electric machine? How many, of engineers even, can explain where the electricity comes from, or how the mechanical power is converted into electrical energy, or what the magnetism of the iron magnets has to do with it all? Take any one of the dynamo-electric machines of the present date—the Siemens, the Gramme, the Brush, or the Edison machine—of each of these there exist descriptions excellent in their way, and sufficient for men already versed in the technicalities of electric science. But to those who have not served an apprenticeship to the technicalities—to all but professed electricians—the action of these machines is almost an unknown mystery. As, however, an understanding of the how and the why of the dynamo-electric machine or generator is the very A B C of electrical engineering, an exposition of the fundamental principles of the mechanical production of electric currents demands an important place in the current science of the day. It will be our endeavour to expound those principles in the plainest terms, while at the same time sacrificing nothing in point of scientific accuracy or of essential detail.

The modern dynamo-electric machine or generator may be regarded as a combination of iron bars and copper wires, certain parts of the machinery being fixed, whilst other parts are driven round by the application of mechanical force. How the movement of copper wires and iron bars in this peculiar arrangement can generate electric currents is the point which we are proposing to make clear. Friction has nothing to do with the matter. The old-fashioned spark-producing "electrical machine" of our youthful days, in which a glass cylinder or disc was rotated by a handle whilst a rubber of silk pressed against it, has nothing in common with the dynamo-electric generator, except that in both something turns upon an axis as a grindstone or the barrel of a barrel-organ may do. In the modern "dynamo" we cannot help having friction at the bearings and contact pieces, it is true, but there should be no other friction. The moving coils of wire or "armature" should rotate freely without touching the iron pole-pieces of the fixed portion of the machine. In fact friction would be fatal to the action of the "dynamo." How then does it act? We will proceed to explain without further delay. There are, however, three fundamental principles to be borne in mind if we would follow the explanation clearly from step to step, and these three principles must be laid down at the very outset.

1. The first principle is that the existence of the energy of electric currents, and also the energy of magnetic attractions, must be sought for not so much *in the wire* that carries the current, *or in the bar of steel or iron* that we call a magnet, as *in the space that surrounds* the wire or the bar.

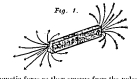
2. The second fundamental principle is that the electric current is, in one sense, quite as much a *magnetic* fact as an electrical fact; and that the wire which carries a current through it has magnetic properties (so long as the current flows) and can attract bits of iron to itself as a steel magnet does.

3. The third principle to be borne in mind is that to do work of any kind, whether mechanical or electrical, requires the expenditure of energy to a certain amount. The steam engine cannot work without its coal, nor the labourer without his food; nor will a flame go on burning without its fuel of some kind or other. Neither can an electric current go on flowing, nor an electric light keep on shedding forth its beams, without a constant supply of energy from some source or other.

The last of these three principles, involving the relation of electric currents to the work they can do and to the energy expended in their production, will be treated of separately and later. Meantime we resume the task of showing how such currents can be produced mechanically, and how magnetism comes in in the process.

Surrounding every magnet there is a "field" or region in which the magnetic forces act. Any small magnet, such for example as a compass needle, when brought into this field of force, exhibits a tendency to set itself in a certain direction. It turns so as to point with its north pole toward the south pole of the magnet, and with its south pole toward the north pole of the magnet; or if it cannot do both these things at once, it takes up an intermediate position under the joint action of the separate forces and sets in along a certain line. Such lines of force run through the magnetic "field" from one pole of the magnet to the other in curves. If we define a line of force as being the line along which a free north-seeking magnetic pole would be urged, then these lines will run from the north pole of the magnet round to the south pole, and pass through the substance of the magnet itself. In Fig. 1 a rough sketch is given of the lines of

Fig. 1.



magnetic force as they emerge from the poles of a bar magnet in iaffis. The arrow heads show the direction in which a free north pole would move. These lines of force are no fiction of the imagination like the lines of latitude and longitude on the globe; they exist and can be rendered visible by the simplest of expedients. When iron filings are sprinkled upon a card or a sheet of glass below which a magnet is placed, the filings set themselves —especially if aided by a gentle tap—along the lines of force. Fig. 2 is a reproduction from nature

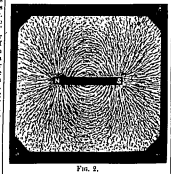


FIG. 2.

of this very experiment, and surpasses any attempt to draw the lines of force artificially. It is impossible to magnetise a magnet without also in this fashion magnetising the space surrounding the magnet; and the space thus filled with the lines of force possesses properties which ordinary unmagnetic space does not possess. These lines give us definite information about the magnetic condition of the space where they are. Their direction shows us the direction of the magnetic forces, and their density shows us the strength of the magnetic forces; for where the force is strongest there we have the lines of force most numerous and most strongly delineated in the scattered filings. To complete this first consideration of the magnetic field surrounding a magnet, we will take a look at Fig. 3, which reproduces the lines of filings as they settle in the field of force opposite the end of a bar magnet. The repulsion of the north pole of the magnet upon the north poles of other magnets would be, of course, in lines diverging radially from the magnet pole.

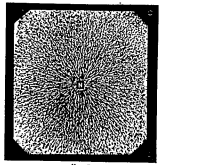

FIG. 3.

We will next consider the space surrounding a wire through which a current of electricity is flowing. This wire has magnetic properties so long as the current continues, and will, like a magnet, act on a compass needle. But the needle never tries to point toward the wire, its tendency is always to set itself broadside to the current and at right angles to it. The "field" of a current flowing up a straight wire is, in fact, not unlike the sketch shown in Fig. 4, where instead of tufted groups we

Fig. 4.

have a sort of magnetic whirl to represent the lines of force. The lines of force of the galvanic field are, indeed, circles or curves which enclose the conducting wire, and their number is proportional to the strength of the current. In the figure, where the current is supposed to be flowing up the wire (shown by the dark arrows), the little arrows show the direction in which a free north pole would be urged round the wire* a south pole would, of course, be urged round the wire in the contrary direction. Now though when we look at the photographs wires, or at any wire carrying a current of electricity, we cannot see these whirls of magnetic force in the surrounding space there is no doubt that they exist there, and that a great part of the energy spent in starting an electric current is spent in producing these magnetic whirls in the surrounding space. There is, however, one way of showing the existence of these lines of force; similar, indeed,

* It will not be out of place here to recall Ampère's ingenious rule for remembering the direction in which a current must flow to make a magnetic needle. "Suppose a man embraces in the wire with the current, and that he turns so as to face the needle, then the north pole of the needle will be deflected towards his left hand."

EXPERIMENTS WITH THE HAND DYNAMO—II.*

By S. H. Borrese.

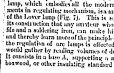
THE "best" light is so called from its form, when produced between two carbon points lying horizontally, being that of a bridge or arch (Ital. *arco*). Fig. 6 represents the "arc" light produced in 1809, by Sir Humphrey Davy, with the battery of the Royal Institution, consisting of 2,000 plates of zinc, each having a surface of 32 square inches. This are exceeded 4in. in length.

The great point to be aimed at, in the production of a good arc light, is the maintenance of a proper distance but when the carbon points when the light becomes unsteady. The voyage of the current (the vibratory motion of the particles) disturbs portions from the positive carbon, and throws them up on the negative carbon; some portion of the carbon is also apparently volatilised, so that the distance between the carbons at last becomes too great for the current to be able to bridge over. To remedy this defect, devices innumerable have been suggested, and patented in the United States.

In the dynamo light at the Exhibition, but will not probably be of any practical use, when an H.P. of about 25 to 40 volts is needed to produce a good steady light.

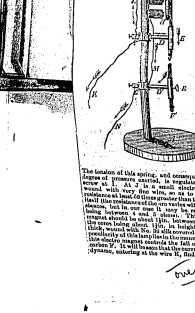
A very simple, and yet effective form of arc lamp, which embodies all the modern improvements in regulating mechanism, is a model of one of the Lever lamp (Fig. 7). This is so simple in its construction that any amateur who can use a file and a soldering iron, can make himself one, and thereby learn more of the principle by which the regulation of arc lamps is effected, than he would gather reading volumes of description. It consists in a base A, supporting a mahogany, basewood, or other insulating standard B, about

Fig. G.



one foot in height, and 3in. in diameter. Two metal stops C and C are fixed 3 inches apart at about 2½in. apart. These carry metal arms D and D to which are attached short pieces of brass tubing F F, through which the carbon rods F and F can just pass freely. The lower carbon can be elevated to any desired height by means of the rack and pinion at F: the fall of the other carbon is prevented by the spring G, which presses a small soft iron armature H against the carbon rod, and thus jams it against the tube.

Fig. 7



The tension of this spring, and consequently the degree of pressure exerted, is regulated by the screw J. At I, a small electro-magnet, wound with fine wire, so as to present a resistance at least 50 times greater than the "arc" resistance, but in our case it may be otherwise, is connected to the rod C above. This electro-magnet should be about 1½in. between the poles, the cross being about 1in. square. The coils, when wound, with No. 36 silk-covered wire, the resistance of this lamp line in the manner in which it is worked, is about that the current from the dynamo, entering at the wire B, finds two paths

* All rights reserved.

EXPERIMENTS WITH THE HAND DYNAMO—III.*

By S. H. Borrese.

"OUR" dynamo is eminently adapted to our experiments with the induction coil, and will work well and easily (or without fatiguing the operator) any coil capable of giving from 1in. up to 3in. spark. It will be found very easy to use a shunt in working these coils; not only because they present resistance (though that, of course, affects the current), as because the best and most constant arrangement of the induction coil entirely cuts off the current from circulating round the field magnets (except on collision of the sliding stopper, unless a shunt is used; and this interruption of the current is always strongly against the production of the best effects, since the field magnets lose the power to get magnetised in the right direction. About 40 feet of No. 36 iron wire will be found to give the proper resistance for any ordinary-sized coil. In order to get the best results, both in this and in other experiments, it will be best to have at least shunts of stated varying resistances. These are easily made of sufficient accuracy by coiling on a bobbin of wood, or paper, about 1in. in diameter, lengths of No. 36 iron wire, which can then be inclosed in short lengths of glass tubing, the extremities of the wire passing through corks placed at each end of the tube. (Fig. 8 shows the arrangement.)

Since the resistance of No. 36, soft iron wire is not nearly 1 ohm to the foot, it follows that by using five inches of the said soft iron wire, in lengths increasing from 1ft. to 5ft., and inclosing each of these in tube, as above described, we produce a series of rough resistance coils of from 1 ohm to 5 ohms approximate, which may be labelled with their several resistances, and used, as circuit or shunt may require. Whichever shunt be used, it must be found to be so connected to the dynamo as to complete the circuit between the armature and field magnets, when the outer or working circuit (which now becomes a derived circuit) is led from the binding screw A, to start with the armature. As it is of importance that the student should thoroughly understand this point, the proper position for the shunt is shown at Fig. 7, where P and P are the field magnets of the dynamo, S being the armature. The wires from which make connection through the commutator to the binding screws A and A. When we are working our dynamo as a series machine against a small and unvarying resistance, we connect the binding screws A' and B with the outer circuit, in which we need a resistance, or a variable, as does also the binding screw A, which is connected with the field magnet binding screw B by the fixed piece C, and from thence in the direction of the arrows (red) by coupling wire F, into F, round P, to B', which is one of the binding screws and for the outer circuit. From thence the current traverses the outer circuit C, and enters the dynamo by the binding screw A', which is connected with the negative brush of the commutator. But if the outer circuit presents too small a resistance, or is variable, so that the quantity of electricity it allows to circulate round the field magnets is insufficient or unequal, then a shunt is introduced at C, and the outer circuit is completed by coupling wire F, binding screw A and A, to whatever work it is

Fig 8

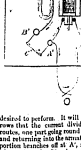


Fig 9

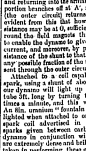

desired to perform. It will be seen by the arrows that the current divides itself along two routes, one part going round A B C F F' C A', the other round the galvanometer, while the other portion traverses C A' A, and passes into the positive terminal of A', and passing into the outer circuit returns at X. It will be evident from this that however great the resistance may be at O, sufficient current will flow round the field magnets through the shunt C, to enable the dynamo to give the due amount of current, and moreover, by increasing the resistance of the shunt to that of the outer circuit, any possible fraction of the current may be sent through the outer circuit.

Attached to a coil capable of giving a 1in. spark, using a shunt of about 1 ohm resistance, our dynamo will light up a Gassiot's vacuum tube 5ft. long by turning the handle about 80 times a minute, and this without any fatigue. An 8in. uranium "fountain" tube is brilliantly lighted when attached to one of the little coils, spark coil advertised in our columns.

The beautiful sparks between carbon points in the dynamo in conjunction with [illegible] are extremely dense and brilliant—more than token in performing these experiments with the coil and dynamo that also be used in heating the given to those who may [illegible] be nearly sure tubes, carbons, &c., as, for [illegible] to break the apparatus [illegible] the shocks inflicted by the coil are extremely severe. A very pretty experiment, illustrative of the power possessed by the rays of high refrangibility, which showed in the electric light, of evoking the phenomenon of phosphorescence, is to arrange the dynamo in connection with the

Scale 120 mm.

574

solution and the regulator resumes its action, but if the [illegible] be turned through the same movement [illegible] it will be found that when the [illegible] the main circuit is re-established, the [illegible] become active and [illegible] the armature [illegible] which causes the lower carbon to ascend also, the shorter [illegible] of course inactive [illegible] the stopping of the positive and bearing of the negative carbon establishes the distance necessary for [illegible] to be interposed, by placing a small phosphorescent tablet (one of any [illegible] sold along with [illegible] between the carbons, and as resistance increases by the lengthening of the arc, but the derived current is interrupted as soon as the [illegible] and opens the circuit; by this arrangement [illegible] the lamp is very prompt in operating the [illegible] Q to its position for locking the upper carbon-holder. Five of these regulators, fed with the best [illegible] Gramme generator for five lights, which we published on page 549 ante, and yielding nearly 1,000 candles, were maintained with air burns power. The [illegible] accompanying this notice have been taken from the *Scientific American*.

AIR-REFRIGERATING MACHINERY.

At the ordinary meeting on Tuesday, the 11th of February, Sir Frederick Bramwell, F.R.S., Vice-President, in the chair, a paper was read "On Air-Refrigerating Machinery and its Applications," by Mr. J. J. Coleman.

The author said that the first practical machine for regulating artificial refrigeration on compressed air was stated by Jonle, Sir William Thomson, Rankine, Clerk Maxwell, and others, and consisted essentially of the fact that atmospheric air having lately been caused to be the vapour of a liquid there was no essential difference in the matter of machines for producing cold, whether air or the vapours of volatile liquids were the agents commonly were employed. Air machines which were in use on board ships afforded a really considerable saving but the [illegible] of the [illegible] point of the liquid, and therefore it was impossible with such machines in get as large a range of cooling as in machines which could be accomplished by air. The machines which Patent required for the liquefaction of oxygen and hydrogen were obtained in sharply defined crystals of crystals of the substances subjected to excess, producing sufficient cold to liquefy air, and by the gradual removal of

In the section of the Association devoted to economic science and statistics (Section F), a highly valuable and interesting paper was read by Professor Silvanus Thompson, D.Sc., "On the Apprenticeship Schools in France," in which the author described in detail the systems adopted in that country of technical education, and the methods in use for the intelligent and intellectual training of artisan apprentices. The paper, which although a lengthy one, we intend, on account of its importance, and the valuable information which it contains, to publish in these columns, was illustrated by a large collection of objects in various branches of industry made by the pupils, as well as by diagrams and results; and to add still more to the practical value, the paper concluded with a number of suggestions for the formation of a sound system of technical education for this country, which would give to the apprentices and artisans of Great Britain the advantages possessed by their Continental brethren with respect to this all-important question. The author laid especial emphasis on the importance of the adoption of a system of instruction based upon drawing, which was, as he expressed it, "the language of the manufacturer, of the handicrafts, and of the constructive industries of all kinds."

The reading of this paper was followed by an interesting and animated discussion, in which Dr. Gladstone, F.R.S., Sir Antonio Brady, Professor Leone Levi, Mr. Britain, and Mrs. Lewis took part, and it was brought to a close by Mr. Mundella, M.P., for Sheffield, who, in an interesting speech, deplored the ignorance which existed in many industries, not only in the minds of the workmen, but in those of the masters and employers of labour; he would, however, express his opinion that the systems of technical training adopted in Germany possessed greater advantages for the English student than those in operation in France.

In the same section Professor Leone Levi read a "Communication upon the Scientific Societies in England to the Advancement of Science in the United Kingdom." Professor Levi commenced his paper by stating that he had been induced to write it in consequence of the renewed attempt to establish in London a building in the metropolis to accommodate the various societies having for their object the advancement of the applied and technical sciences. In it he stated that although in the seventeenth century there were only two scientific societies in this country, there are, at the present time, scientific societies which can claim no less than 60,000 members, or deducting 10 per cent. as representing the proportion of that number who belong to several societies, there are no less than 54,000 individual members. In the discussion which followed, Sir Rawson Rawson, Mr. Hurst, Mr. Britain, and Mr. Mundella, M.P., took part. The last-named gentleman in the course of his remarks said that he considered the letters "F.R.S." a much greater distinction than "M.P." for it could only be the acquisition of great and solid intellectual attainments that could entitle a man to that honour, and he was afraid he would hardly be justified in claiming the same qualification for all the members of the distinguished assembly of which he had the honour of being a member.

In Section G the business commenced on Thursday last by the delivery of the presidential address by Mr. J. Robinson, President of the Institution of Mechanical Engineers. As, however, we publish on another page this interesting address, which was a review of the applications of steel, we need only refer to it in this place. At its conclusion a vote of thanks, proposed by Sir Joseph Whitworth, Bart., F.R.S., and seconded by Mr. W. H. Barlow, C.E., F.R.S., was passed by acclamation.

The first paper read in Section G was one by Mr. Baldwin Latham, C.E., "On the Temperature of Town Water Supplies." In this paper, which we publish on page 168, the author pointed out that the increase of temperature in the supply beyond 53 deg. Fahr. caused the water to have unwholesome properties, and that the temperature of water in a town supply is wholly independent of the temperature of the water at its source of supply, and that without exception, the temperature of the water is the same as that of the ground at the spot and at the depth where the pipes are laid. He called attention to the fact that the temperature of the water supply of a town was of the highest importance from a sanitary point of view, and one which he would be well to investigate very thoroughly in regard to its influence upon certain classes of disease.

Mr. James Glaisher, F.R.S., stated that having been long connected with the office of the Registrar-General, he had often been part of his duty to take the temperature of the Thames water, and he corroborated the remarks of Mr. Latham with regard to the country aspect of the question. It had, he said, long been a recognised fact that cholera and like allied diseases never showed themselves to any great extent until the temperature of the Thames water reached 62 deg. Fahr. He was greatly in favour of the employment of larger water mains than were generally employed, as being much slower in acquiring the temperature of their surroundings than pipes of smaller sectional area.

Captain Douglas Galton, C.B., F.R.S., remarked that water supply pipes should be kept as much as possible below the ground, and he thought that the facts recorded in the paper as well as in the remarks of the speakers who had joined in the discussion constituted a strong argument for the substitution of cisterns by a constant service system.

The President, having thanked Mr. Latham on behalf of the section, called on Mr. Joseph Lucas to read his paper "On the Quantitative Elements in Hydrography." The reading of this paper, which we intend to print *in extenso* on an early occasion, gave rise to a discussion, in which Mr. Baldwin Latham, Mr. C. W. Merrifield, Captain Douglas Galton, and Mr. Grantham took part, and a vote of thanks having been accorded to the author, the President called upon M. Bergeron to read his paper "On Leon Francq's Friction Locomotive," in which the motive power is obtained from a reservoir containing about 700 gallons of water heated by a temperature corresponding to a pressure of 224 lb. to the square inch.

In the discussion which followed, Mr. W. H. Barlow said he considered the system worthy of the most careful consideration, for engines of this class, without fire and without smoke, would be of great value on lines on which there were a number of tunnels.

Captain Galton said he had seen the engine at work in Paris, and he had been most favourably impressed with its working, and he believed that when the use of steam on street tramways is sanctioned by Parliament, engines, such as that described in the paper, would come into general use. After a few remarks from other members of the section the Thursday's business of Section G was brought to a close by a cordial vote of thanks to the author of the paper.

In the evening a soiree was given to the members and associates by the Master Cutler of Sheffield and the Cutlers' Company in the Cutlers' Hall. The gathering was purely a social one, commencing with a promenade and ending with a ball, and as there were no objects of a scientific character exhibited we need only refer to it as having taken place.

Leaving until next week an account of the proceedings of sections on Friday the 22nd of August and following days, we must call the attention of our readers to the deeply interesting discourse of Mr. William Crookes, F.R.S., upon radiant matter, which was delivered to a large audience in the Albert Hall on the evening of that day, and a part of which we publish in our present issue on page 162. It must, we think, be admitted on all sides that Mr. Crookes's lecture, illustrated as it was by a series of the most beautiful experimental illustrations that have ever been brought before an audience, will hereafter be looked upon as the characteristic feature of the Sheffield meeting of the British Association.

To the readers of this journal there was not anything absolutely novel in the facts recorded in this lecture, for the reason that the splendid researches of Mr. Crookes which he brought forward the other evening have already been described and illustrated by us in our articles on "The Trajectory of Molecules,"* and on the last convocazione of the Royal Society,† but such researches can never lose their freshness, and such experiments provide intellectual enjoyment the more often they are seen, and although many of the illustrations had been demonstrated before the Royal Society and elsewhere, they were shown on such a grander scale at Sheffield that they were all, in a very important sense, new experiments. Nothing could have been more successful than this lecture; not one illustration failed, and we venture to say that seldom has it fallen to the lot of a scientific demonstrator or his assistant—and it would be impossible to overpraise the merits of Mr. Crooke's lecture in the case of Mr. Charles H. Gimingham, who not only has manipulated most of the apparatus employed, but has himself constructed with a skill which belongs to him alone the most important and delicate part of it,—seldom we would repeat has it fallen to the lot of a scientific lecturer or his assistant to perform before a large audience such delicate and different demonstrations, and Mr. Crookes must be heartily congratulated not only for the success that he achieved but for the enthusiastic appreciation with which his lecture and illustrations were received by a large and distinguished audience.

At its conclusion a very hearty vote of thanks was proposed by Mr. Spottiswoode, President of the Royal Society, and seconded by Mr. Johnstone Stoney, who was received with loud applause, as it was he who first pronounced the now universally accepted theory of the physical action of the radiometer, out of which the many recent researches of Mr. Crookes have been extended, and to which they bear so intimate a relationship. The vote of thanks having been carried by acclamation, Mr. Crookes, in a brief acknowledgment, said that it was difficult to say which afforded to the scientific investigator the greatest pleasure, the discovery of some philosophical truths or the bringing them before such an audience as the one he now addressed.

LIGHTING BY ELECTRICITY.—NO. IV.

(Lighting Machines Continued.)

We have in former articles described the early magneto-electric machines of Holmes and of the Société d'Alliance* and the single current machines of Gramme† and Siemens.‡ Each of these machines is typical of a class, the last named forming a class by itself. We now come to speak of an order of machines to which the name multiple circuit has been applied, and to which order belong the machines of Lontin, Wallace-Farmer, and Wilde, as well as the multiple circuit machines of Gramme and Siemens.

In the Lontin machine, which we illustrate on the next page, the revolving armature is in the form of a stalagmoid wheel consisting of a central bore C, Fig. 1, into which are fixed ten or more radial bars of soft iron, circular in section and slightly conical in form, marked in the drawing D D D. Each of these radial spokes is wound with a coil of insulated copper wire, the ends of which are connected together in series, and to a central commutator. The armature wheel is fixed on a shaft and revolves in the magnetic field of two powerful electro-magnets A A first virtually into a knee-plate of iron by which they become the two limbs of a "horseshoe" electro-magnet. The ends of the radial magnetic cylinders or fixed valve segments very close to and accrete from the poles of the inducing magnets A A, being of their point of closest proximity with the ends of the line N.N, Fig. 1, by Lenz's law, a coil approaching a north pole of a magnet induces a current of electricity induced in it in one direction, and when receding from the same pole the induced current in the opposite direction, and a coil receding from a north pole has a current induced in it in the same direction as a similar coil approaching a south pole, and *vice versâ*. Bearing these laws in mind, and referring to Fig. 1, it will be seen that when the insulated and revolving in the direction of the arrows, S S, the radial bobbins above the horizontal line N N are receding from the north pole and approaching the south pole, while those below the line N.N. are receding from the south pole; the north pole and approaching the south pole; the currents induced, therefore, in all the bobbins above the line N.N. are similar in direction to one another, but inverse to those below the line N.N. The coils in the arrangement shown in the Gramme machine, coupled together in series as in the Siemens machine, and each pair of contiguous coils in series, therefore in each sector I of the cylindrical commutator, there being as many sectors as there are coils, and insulated from one another by thin strips of ebonite N N. Against the surface of this commutator collectors are pressed by means of springs, the one taking

THE "BRUSH" SYSTEM OF ELECTRIC LIGHTING.—No. I.

THE Brush system of electric lighting which during the last two years has in the United States of America been developed into a very important commercial industry, is one of the most interesting systems of illuminating by electricity that has yet been before the public, and we are glad to see that it is at last becoming more and more appreciated in this country, and promises under very able and influential management to take a leading position among the lighting systems of Europe. It has for upwards of twelve months been employed for illuminating the terminus of the Great Eastern Railway at Liverpool-street, and it has within a few weeks been adopted by the Great Western Railway Company for their Paddington Station, and the Charing Cross terminus of the South Eastern Company is now illuminated by the same system. It is about to be applied to light a large area of the City of London, where it will be in competition with both the Siemens and Jablochkoff systems, each of which will have a district of similar area of the City to illuminate, so that the public will soon have an excellent opportunity of comparing it with all the important systems that have been introduced, for the Gramme system is at the same time to be employed at the Cannon-street Station, where the electric currents will be utilised in another distinctive form of lamp.

The Brush, like the Siemens system, includes both generator and regulator peculiar to itself, and may therefore be looked upon as complete in itself, differing in that respect from all those so-called systems which are represented by either a particular form of machine or a special arrangement of lamp, and like the proprietors of the Siemens system, the Brush Company manufacture their own carbons, making the whole installation still more peculiar to themselves.

The Brush machine, a general view of which is given in Fig. 1 (see next page), possesses some points of resemblance to the dynamo-electric machines of Gramme and of Wallace-Farmer, as well as to the magneto-electric machines of M. de Meritens, while at the same time its principle of construction differs from that of all others, and confers upon it at once a special excellence and its originality.

Its point of resemblance to M. Gramme's machine* consists in the fact that its armature is of annular shape, a form of construction first adopted to the purpose by M. Gramme some thirteen years ago. The Brush armature differs, however, from the Gramme ring in the arrangement and disposition of the bobbins of wire with which it is wound, as well as in the way in which the several coils are connected with one another. In the Gramme armature the coils are wound contiguously to one another, so as entirely to envelop the iron core, hiding it completely from view, and they are permanently connected to one another in consecutive series. In the Brush armature the dimetrically opposite bobbins are alone permanently connected together, and a current generated in one pair of bobbins does not necessarily traverse all the others, and in fact never does, as will be pointed out in the course of this notice. Again, the individual coils are separated from one another by a considerable sector of the iron ring, which is of larger sectional area between the coils (see Fig. 2), so that in the revolution of the armature within the magnetic field the coils alter, inasmuch as masses of iron which from their enlarged section are brought into so close proximity to the poles of the field magnets as are the armature of the coils themselves. It is this difference from the Gramme ring which constitutes the similarity between the Brush armature and that of M. de Meritens,† but the Brush machine differs in all other essential respects from the latter machine in the disposition of its coils, in its method of connection, in the method and arrangement of the magnetic field, and in the continuous nature of its current.

The Brush machine however differs altogether from the Gramme generator in the disposition of its field magnets and the relative positions of the revolving bobbins and the magnetic field. In the disposition of its magnets the Brush machine more nearly resembles the Wallace-Farmer apparatus, but their form is entirely different, and the armature of the Wallace-Farmer bears no sort of resemblance to the Brush ring, its coils being more allied to those of M. Lontin's‡ machine than to any other of the characteristic generators. Having thus pointed out the positions occupied by the Brush machine with respect to other typical generators, showing wherein it approaches and wherein it departs from the machines of other systems, we will proceed to describe its construction.

The most characteristic feature of the Brush machine lies in the form and construction of its armature, which consists of a cast-iron ring, the cross section of which is generally rectangular, but in the direction of its circumference it is alternately wide and narrow, as shown in the sketch, Fig. 2, which represents a portion of the iron armature ring and explains its construction better than can be given by description. On reference to this figure it will be seen that the ring is divided up into as many sectors as there are bobbins to be wound, by a number of rectangular depressions or *grooves*; in these the coils of insulated copper wire are wound until the groove is filled up and the flat converging recesses become flush with the face of the intermediate thicker portions or pole-pieces by which they are separated from one another. Fig. 2 is a cross section of one side of the ring taken

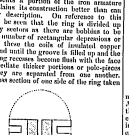

FIG. 3.

through one of these portions, and it will be observed on reference to both figures that the intermediate thicker portions of the ring are grooved out by a series of deep concentric grooves, the object of which is partly to reduce the mass and lessen the weight of the revolving armature, partly for the purpose of ventilating the ring and thus carrying away a portion of the heat generated by the working of the machine, but chiefly for the localisation and isolation of local currents generated by induction in the iron and which would tend not only to reduce the efficiency of the machine by diminishing the magnetic capacity of the armature, but also to produce a heating of the ring, and therefore of the coils, whereby a portion of the current would be lost through their resistance being increased. For a similar reason the periphery of the ring is grooved out deeply so as almost to sever the ring; by this means all cross currents are effectually cut off and induction currents are compelled to flow in directions which are not detrimental to the efficiency of the machine. This again increases the area of radiating or cooling surface, and consequently helps to prevent the armature becoming overheated.

In what is called the sixteen-light machine, which may be regarded as the normal size of the Brush generator, the armature ring is 20 in. in diameter, and it is wound with eight radial coils of cotton-covered copper wire of No. 14 B.W.G., whose visible planes radiate from the axis of rotation, being distributed round the ring at equal angular distances apart of 45 deg. Each coil contains about 900 ft. of wire weighing about twenty pounds, and is wound in the rectangular grooves or spaces shown in Fig. 2, filling up the spaces completely so that the vertical faces of all the coils are flush with the vertical faces of the thicker portions of the iron ring. Fig. 3 is a sketch of the armature ring with all its coils wound, which must be looked upon rather as an explanatory diagram than as an illustration of the proportions of this part of the apparatus. The two sides of each groove, and therefore of each coil of wire, are parallel to the centre line or radial plane of the coil, and by the adoption of that form of bobbin one of the practical difficulties in the winding of annular armatures of the ordinary form is avoided. All the coils are, like those in the Gramme machine, wound in the same direction.

Fig. 4 is a diagram illustrative, not only of the distribution of the coils around the ring, but of the method by which the connections are made; the inner end of each of the coils is connected by a wire to the inner end of the corresponding coil, at the opposite end of the same diameter of the ring, and the outer ends of all the coils are brought through the shaft of the machine, and are connected to corresponding portions of the commutator, where the currents are collected by suitably placed copper plates or brushes. Referring to the diagram, it will be seen that the inner end A^1 of the coil 1 is connected to A^5, which is the inner coil of the coil 5; A^5 is connected to A^9, A^9 to A^1, and so on round the ring, and the outer ends B^1, B^5, B^9, &c., are connected to the commutator by conducting wire insulated from one another. The two free ends of each pair of diametrically opposed coils are, after passing through the shaft of the machine, attached respectively to two diametrically opposite segments of the same commutator, which segments are insulated from one another and from any other pair of coils. The commutator, which is attached to and rotates with the driving shaft of the machine, consists of a set of separate copper rings or flat cylinders, of which there are as many on the shaft as there are pairs of coils on the armature, and each of these cylinders consists of two segments insulated from one another on one side of the shaft by a small air space about one-eighth of an inch wide, and on the other by a piece of copper separated from the segments by two smaller air spaces. The arrangement is shown in Fig. 6, in which A and B are the two segments connected respectively to corresponding coils on opposite sides of the armature, and

FIG. 5

FIG. 6.

attached by an insulating material to the shaft S: C is the copper insulating piece, the object of which is to separate either of the segments, or commutators, which press upon the periphery of the commutator, from either of the segments during the interval occupied by one pair of coils passing the vertical, or in other words through the neutral portion of the magnetic field; this occurs twice in each revolution of the armature, and therefore of the commutator. At the time when any pair of bobbins is in this way cut out of the general circuit, their own circuit is open, so that no current can flow through or be induced in them. By this most ingenious arrangement each pair of coils has in succession in each revolution a period of rest equal to one-quarter of a revolution, and has a current passing through it only for 75 per cent. of the time the machine is running; to it is, in a great measure, due the very small development of heat in the working of the Brush machine, and it presents also another important element of efficiency to the machine, namely, that each pair of bobbins as it passes the neutral portion of the magnetic field, and is therefore incapable of doing work and contributing electromotive force to the general current, is itself cut out of the circuit, and thus two causes operating against the efficiency of the machine are eliminated; the first is one common to most generators which have, like that in the Gramme machine, a permanently closed circuit, namely, that the currents generated in the bobbins have two routes open to them, the one through the conductors and commutator to the brushes, and the other through the idle bobbins, and thus by a species of short

ON THE MECHANICAL PRODUCTION OF ELECTRIC CURRENTS.—No. II.

In the first article on this subject, published last week (see ENGINEERING, page 77), we described how the electric current, or rather the wire through which it flows, possesses for the time magnetic properties, and is surrounded by lines of force. It was further shown how magnetism can be produced from electric currents, a spiral coil of wire through which a current is sent acting like a magnet.

The next point to be studied is the magnetic property of a single loop of the wire through which an electric current flows. Fig. 9 represents

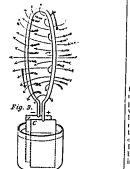

Fig. 9.

single voltaic cell containing the usual plates of zinc and copper dipping into acid to generate a current in the old-fashioned way. The current flows from the zinc plate through the liquid to the copper plate, and from thence it flows round the wire ring or circuit back to the zinc plate. Here the lines of magnetic force in the surrounding space are no longer only whirls like those drawn in Figs. 4 and 6, for they react on one another and become nearly parallel where they pass through the middle of the ring. The thick arrows show the direction of the electric current, the fine arrows are the lines of magnetic force, and show the paths along which a free north pole would be urged. All the front face, where the arrow-heads are, will be like the south pole of a magnet. All the other face of the ring will be like the south pole of a magnet. Our ring resembles a flat magnet, one face all north pole the other face all south pole. Such a magnet is sometimes called a "magnetic shell."*

Since the circuit through which the current is flowing has these magnetic properties, it can attract other magnets or repel them according to circumstances.

If a magnet be placed near the circuit, so that its north pole N is opposite that side of the circuit which acts as a south pole, the magnet and the circuit will attract one another. The lines of force that radiate from the end of the magnet, curve round and coalesce with some of those of the circuit. It was shown by the late Professor Clerk Maxwell that every portion of a circuit is acted upon by a force urging it in such a direction as to make it enclose within its embrace the greatest possible number of lines of force. This proposition, which has been termed "Maxwell's Rule," is very important, because it can be so readily applied in many cases, and will enable one so easily to think out the actual reaction in any particular case. The rule is illustrated by the sketch shown in Fig. 10, where a bar magnet has been placed with its north pole opposite the south face of the circuit of the coil. The lines of force of the magnet are drawn into the ring and coalesce with those due to the current. According to Faraday's mode of regarding the actions in the magnetic field there is a tendency for the lines of force to shorten themselves. This would occur if either the magnet were pulled into the circuit, or the circuit were moved up towards the magnet. Each attracts the other, and whichever of them is free to move will move in obedience to the attraction. And the motion will in either case be such as to increase the total number of lines of force that pass through of the circuit. Lest it should be thought that Fig. 10 is

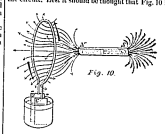

Fig. 10.

inverted or overdrawn, we reproduce as actual magnetic "field" made in the manner described in the preceding article. Fig. 11 is a kind of sectional view of Fig. 10, the circuit being represented merely by two circular spots or holes above and below the middle line, the current flowing towards the spectator through the lower spot, and passing in front of the figure to the upper hole where it flows down. Into this circuit the pole N is attracted, the tendency being to draw as many lines of force as possible into the embrace of the circuit.

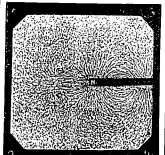

Fig. 11.

So far as the reasoning about these mutual actions of magnets and currents is concerned, it would therefore appear that the lines of force are the really important feature to be understood and studied. All our reasons about the attractions of magnets would be equally well thought out if there were no corporeal magnets there at all, only collections of lines of force. Bars of iron and steel may be regarded as convenient conductors of the lines of force; and the poles of magnets are simply the places where the lines of force run out of the metal into the air or *vice versâ*. Electric currents also may be reasoned about, and their magnetic actions foretold quite irrespective of the copper wire that acts as a conductor: for here there are not even any poles; the lines of force or magnetic whirls are wholly outside the metal. There is an important difference, however, to be observed between the case of the lines of force of the current, and that of the lines of force of the magnet. The lines of force of the magnet *are* the magnet so far as magnetic forces are concerned; for a piece of soft iron laid along the lines of force thereby becomes a magnet and remains a magnet as long as the lines of force pass through it. But the lines of force crossing through a circuit are not the same thing as the current of electricity that flows round the circuit. You may take a loop of wire and put the poles of magnets on each side of it so that the lines of force pass through in great numbers from one face to the other, but if you have them there even for months and years the mere presence of these lines of force will not create an electric current even of the feeblest kind. There must be motion to induce a current of electricity to flow in a wire circuit.

Faraday's great discovery was, in fact, that when the pole of a magnet is moved into, or moved out of, a coil of wire, the motion produces, while it lasts, currents of electricity in the coil. Such currents are known as "induced currents"; and the action is called magneto-electric "induction." The momentary current produced by plunging the magnet pole into the wire coil or circuit is found to be in the opposite direction to that in which a current must be sent if it were desired to attract the magnet pole into the coil. If the reader will look back to Fig. 10 he will see that a north magnet pole is being attracted in from behind into a circuit round which, as he views it, the current flows in an opposite sense to that in which the hands of a clock move round. Now, compare this figure with Fig. 12,

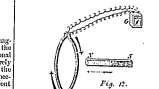

Fig. 12.

which represents the generation of a momentary induced current by the act of moving the north pole N towards a wire ring, which is in this case connected with a little detector galvanometer G. The momentary current flows round the circuit (as seen by the spectator from the front) in the *same sense* as the movement of the hands of a clock. The induced current which results from the motion is found, then, for he is in a direction exactly opposed to that of the current that would itself produce the same movement of the magnet pole. If the north pole instead of being moved towards or into the circuit were moved away from the circuit, this motion will also induce a transient current to flow round the wire, but this time the current will be in the same sense as that in Fig. 10, in the opposite sense to that in Fig. 12. Pulling the magnet pole away sets up a current in the reverse direction to that set up by pushing the pole nearer. In both cases the currents only last while the motion lasts.

Note in the first article it was pointed out that the lines of force of the magnet indicate not only the direction, but the strength of the magnetic forces. The stronger the pole of the magnet is, the greater will be the *number of lines of force* that radiate from its poles. The strength of the current that flows round a circuit is also proportional to the number of lines of force which are thereby caused to pass (as in Fig. 9) through the circuit. The stronger the current, the more numerous the lines of force that thread themselves through the circuit. When a magnet is moved near a circuit near it, it is found that any alteration in the number of lines of force that cross the circuit is accompanied by the production of a current. Referring once more to Fig. 10, we will call the direction of the current round the circuit as that figure the *positive* direction; and to define this direction we may remark that if we were to view the circuit from such a point as to look along the lines of force in their own direction, the direction of the current round the circuit will appear to be the same as that of the hands of a clock moving round a dial. If the magnet N S be now drawn away from the circuit so that fewer lines of force pass through the circuit, experiment shows the result that a current flowing in a contrary sense will be for the moment increased in strength, the former in strength being proportional to the rate of *decrease* in the number of lines of force. Fig. 10, on the other hand, if the magnet were pushed up toward the circuit, the current in the circuit would be momentarily reduced in strength, the reduction in strength being proportional to the rate of increase in the number of lines of force.

Similar considerations apply in the case of the simple circuit and the magnet shown in Fig. 12. In this circuit there is no current flowing so long as the magnet is at rest; but if the magnet be

* The rule for telling which face of the magnetic shell (or of the loop circuit) is north and which south in its magnetic properties is the following. If as you look at the circuit the current is flowing in the same apparent direction as the hands of a clock move, then the face you are looking at is a south face. If the current flow the opposite way round to the hands of a clock then it is the north pole face that you are looking at.

ON THE MECHANICAL PRODUCTION OF ELECTRIC CURRENTS.—No. III.*

We have in two preceding articles (see pages 37 and 101 *ante*) explained how by expending mechanical power in moving a coil of wire past the pole of a magnet, or by moving the pole of a magnet past a coil of wire, we can produce momentary currents of electricity in the coil. We have insisted upon explaining this action by observing the lines of force in the surrounding space, and laid down the rule that the strength of the current so induced in the circuit was proportional to the rate of decrease in the number of lines of force that cross through the circuit.

It will have been observed that in all these actions it is the *relative motion* of magnet and coil that is concerned. It matters not whether the magnet moves towards the coil or the coil towards the magnet, the result is the same, an increase in the lines of force threading through the coils, a decrease in the potential energy of the system, and the production of a momentary inverse current. In the actual construction, however, of almost every kind of dynamo-electric machine, the magnets are fixed while the coils move. This is merely for the sufficient reason that the coils are usually lighter than the magnets, and therefore it would be absurd from an engineering point of view to make the moving parts heavier than the fixed parts. In the generators of Pacinotti, Gramme, Wilde, Siemens, Brush, and Edison, the magnets are fixed while the coils rotate. In Lontin's dividing machine and in a few other generators, however, there is an exception. The magnets attached to a central axis revolve, while the numerous coils in which it is desired to generate currents are fixed upon an external frame.

The next step in explaining how the production of continuous currents in one direction is accomplished in a typical generator will be a consideration of the effect of moving a ring of wire up to a magnet and passing it over its pole.

In Fig. 13 is shown a single ring or coil of wire to serve as a circuit, and beyond it a magnet is shown with its north pole facing the ring. From what has been already laid down it is easy to see what will be the result of moving the ring along towards the magnet. While the ring approaches the north pole, as in the first case of the figure, the lines of force that thread through the ring will be increasing in number, and there will be an *inverse* current (*r*—one which is in a direction inverse to that which would cause the pole N to be attracted; compare the figure of case I with Fig. 10, and note the direction of the arrows). Moreover, even after the ring has been moved as far as the pole N there will still be an inverse current so long as the ring by moving forward is increasing the number of lines of force that it embraces. Comparison with Fig. 2 and Fig. 11 will show that there will be an increase in the number of lines of force until the ring has got as far as the centre or neutral line of the magnet. The second figure of Fig. 13 represents matters up to

Fig. 13.

that point. But now if the forward motion of the ring be continued towards the pole S and beyond it, the number of lines of force that thread themselves through the ring will diminish, and therefore from the moment that it passes the middle point of the magnet a direct current will be induced in it, as shown by the arrows in cases 3 and 4, and there will continue so long as the ring recedes from S.

Again, suppose we have our ring or coil between the two powerful magnetic poles, as indicated in Fig. 14. We will suppose that our coil is moving in a circular path between the poles S and N, which are respectively a south and a north pole. The lines of force will run across in almost straight lines from N to S. We will consider what occurs in the coil as it moves round the upper half of the circular path, its first position being on the left, its last horizontal with its plane very nearly along the lines of force, so that almost none of them pass through it. As it rises and turns round the number of lines of force that thread through the coil increases until it arrives at c^1, where the number

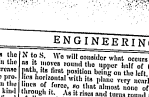

Fig. 14.

that pass through is a maximum. All this time an inverse current will, therefore, be generated in it. After passing c^1, and although it is getting nearer N, the number of lines of force that cross through the coil are decreasing, because it is gradually turning round flat-ways again. From c^1 onwards there will, therefore, be a direct current induced in the coil. Nor does the direct current cease when the coil arrives at the point nearest N, for now, though not shown in Fig. 14, as the coil goes along the lower semicircle the lines of force will begin again to thread through it, but this time they enter the other side of the coil to that which they entered before. There will, therefore, be an increase in the number of lines of force applied negatively, which is, of course, equivalent to a still further decrease. This will go on until the coil arrives at c^2, where the negative increase is a maximum. All the way round the right-hand half of the figure, from c^1 to c^2, there will be a direct current induced in the coil. From c^2 onward and round the left-hand half of the figure up to c^1 there will be an inverse current generated. To render such a some device is needed to turn the inverse currents on the left-hand half so that they shall flow into the wires—that go, say, to feed an electric light—in the reverse way to that in which the direct currents flow into them. For if we never find which is already flowing we thereby bring it into the *direct* relation. The device for accomplishing this end is called a *commutator*, and the line $c^1 c^2$, which marks out the boundary between the currents that are direct and those that are inverse, is known as the "line of commutation."

Fig. 15 is a skeleton diagram of the working parts of a Gramme dynamo-electric generator; it is drawn from a model devised by Professor Silvanus Thompson, of Bristol. The well-known ring armature employed in all the machines of Gramme, as well as in the earlier generator of

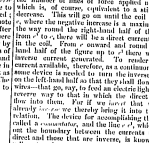

Fig. 15.

Pacinotti, and the later machines of Schuckert, Brush, and Burgin, is the principal feature. It rotates between the poles S N of an electro-magnet of a U form with vertical limbs. The commutator consists of a number of separate bars or strips of copper fixed round the periphery of the axle, while above and below are the contact-brushes which touch the uppermost and lowermost pieces of the commutator respectively. In the model the ring is encrypped by a continuous helix of twelve turns; each one of these twelve turns being connected with one of the twelve copper strips of the commutator. In the drawing the armature is supposed to rotate in the same direction as the hands of a clock. The separate turns or coils in the upper half of the ring armature are therefore moving from S towards N, while those of the lower half are moving from N towards S. As in Fig. 14, so here, there will be direct currents generated in all the coils that are on the right-hand side of the diameter of commutation $c^1 c^2$, and inverse currents in all the coils on the left. The little arrows show the directions of these currents. By following out the various turns of the spiral it will be seen that the separate currents induced in the individual turns of the spiral on the left of $c^1 c^2$ are in the same direction along the wire, and therefore all help one another in producing a strong current, though the electromotive force in each may not be equal. A fashion, having one way of helping another in unison strong pull, though the individual horses may not be equally strong. In these coils the strongest induced electromotive force is, as a matter of fact, in the right-hand half of the spiral the individual currents are all moving in the other direction. Up each side of the ring armature, therefore, there is a strong current flowing, drawing electricity from the lowest point and urging it towards the topmost points. Now the lines of the commutator, which are here represented cut-on in a ring surrounding the axle, are all separate and insulated from one another and from that axis. If electricity were to flow into one of them it would have to flow back again, for there is nowhere for it to flow to; the bars of the commutator local nowhere. This is, however, not the case for the two bars of the commutator first occupied the highest and lowest points. They touch against the contact brushes which communicate with wires of the external circuit. So the electricity that flows up both right and left of the ring armature will flow into the upper contact brush and thence into the leading wire of the circuit, which therefore has a constant current urged though it. A corresponding action goes on at the lower contact brush; from this point electricity is drawn both to the right and to the left, being supplied by the inner wires of the circuit. The current thus furnished is practically continuous; for though the contact is made first against one bar of the commutator and then against another as fast as they arrive at the line $c^1 c^2$, it is clear that the currents on the two sides of the ring armature will always be flowing towards that point at which the contact is made. Neither is there any break in the continuity of the current generated, because one bar of the commutator does not leave off to touch the brushes until the next bar came up to contact, and because there always are a certain number of turns of the spiral both on the right and on the left in which the elementary currents are being induced. In the actual dynamo-electric generators the coils of the armatures are of course made up of many turns of wire. In the common Gramme ring, for example, there are hundreds or thousands of turns, and these are grouped in twenty-four sections, the wire at the end of each section being joined to the wire at the beginning of the next, and the junction connected directly with one of the twenty-four bars of the commutator.*

Up to this point nothing has been said specifically about the best way of making the magnet poles S and N as powerful as possible. All our later arguments simply treated N as the north pole and S as the south pole of a strong magnet. And in the earliest machine for producing currents then by the mechanical movement of coils in the presence of magnets, the magnets used to produce the requisite "field" of force were ordinary magnets of hard steel. Hence the name of "magneto-electric machine" assigned to the older instruments invented by Pixii, Saxton, Holmes, Nollet, and Siemens. Hence also arose the name "magneto-electricity" for the currents produced by induction in these machines; for it was at first thought by some that the electric currents that were generated in these *other* machines, and which consisted of *rapidly* alternating currents, were due to some kind of electricity other than that which flowed round the coils of famously out of a voltaic battery. But we know now that electricity, whether the same be frictional, voltaic, magnetic, or thermal, is all the same. The term magneto-electricity is therefore happily dropping out of use. A little later, machines were made in which permanent steel magnets were replaced by electro-magnets. Generators on this principle were constructed by Wilde and by Ladd. A small

* The reader, of course, knows that there are other armatures besides the ring armatures of the Pacinotti, Gramme, and Brush machines; there are, for example, the drum armatures of the Siemens machines of modern type, and of Edison's generators. Their action can be explained on the same manner, however.

DESCRIPTION OF AN ELECTRO-MAGNETIC ENGINE FOR TURNING MACHINERY.

A CORRESPONDENT, referring to a statement made in our issue for September 15th, asks for further particulars of Sturgeon's electro-magnetic engine. As this was one of the first electro-magnetic engines, we give the following extract from notes our predecessor, in October, 1850, Vol. I., p. 73. Sturgeon's "Annals of Electricity," which is out of our readers' being sure that it will interest a wider circle.

"Fig. 17 represents a steel permanent horse-shoe magnet of the form of the engine. The two opposite corners of the base board are fitted with two upright pillars, which carry a brass cross piece, in the centre of which is a screw, the point of which plays within a small cup of steel, which turns freely in two metallic caps, one of which is in the centre of the base board, and the other at the centre of the cross piece. About half way up the shaft are two circular channels, one above the other, as seen in the figure. Through the centre of these channels, and at right angles to their planes, the shaft passes, and is fixed to them. Lower down, the shaft passes through the centre of an opening in the cross piece, supported by two short pillars. On this cross piece, and concentric with the shaft, are fixed four equidistant metallic plates, supported by screws, each by narrow radial openings. Near the top of the shaft, and at right angles to it, is fixed a compound bar magnet, each magnet of which is about eighteen inches long, one inch broad, and half an inch thick. Near to the bottom of the shaft is fixed another similar compound magnet, with its poles in the opposite direction to the former. Its poles coincide with the shaft, and at an equal distance from each other, are fixed in the base board the lower extremities of four cylindrical bars of soft iron, each of which is enclosed by six coils of copper wire. The coils under each cylinder are connected to each other by intervening ones of silk. Each set of extremities of these copper wires is collected to one each copper wire from the coils and is of the temporary magnets; it will by this means be attracted by the former, and at the same time repelled by the latter. Hence it will be urged by both these forces towards the pole A. If now the circuit be completed, so that the voltaic connection be broken from before the pole N arrives at A, the attraction of the iron bar will become necessary, but the momentum of the iron will carry the pole N to B beyond the neutral point. Now conceive that the pendent wires have been carried from their two contrasted plates to the next in succession. The currents by this means have been reversed in the coils, and a corresponding reversion of polarity must take place in the vertical iron bars; hence when the pole N has just passed the first bar, and whilst still in motion by its acquired momentum, it will again be urged on by two other forces, in a similar manner as they do the first, after the circuit being changed by polarity, it will now repel the pole N at and draw it round, whilst at the same time it will be attracted by the next bar in succession. And in consequence of similar changes of polarity taking place in all the four bars, the pole N will be continually revolving. All that has been said respecting the pole N applies equally to the opposite pole S of the same magnet. So that by this means the magnet and its appendages are continually urged on by two successive attractions and repulsions; and by considering that the lower magnet N S is, by the contrivance also urged on at the same time and in a similar manner, by four other like forces, it will easily be understood that the two magnets, with the shaft to which they are attached, are kept in motion by eight forces, four of which are attractive and four repulsive. Such is the contrivance for keeping the machine in motion. To the upper end of the shaft is attached a vertical spindle, carrying an endless screw near its upper extremity, and revolving in the shaft's bracket, in a collar in the upper cross piece. Near to the lower end of this spindle is a fly with three arms, equidistant from each other, and each terminating with a heavy brass crescent. It was originally the fly of a roasting jack. The endless screw works in the teeth of a toothed wheel, also a part of the old jack. The other of this wheel runs in a frame attached at right angles to the upper cross piece. This engine was constructed in the autumn of 1832, and was exhibited for the first time in London, on March 23rd, 1833, at a lecture on electro-magnetism, which I delivered at the Society Library and Scientific Institution. And notwithstanding its then rude appearance, the Committee were so highly pleased with its structure and performance, that they expressed a wish to have it brought forward again, and hear it explained as soon as there was another opportunity. I was consequently honoured with an engagement to continue and extend my course of lectures in the following June; and in the interim my engine was worked well, and excited a great deal of curiosity among the scientific gentlemen who did believe me to be a fortunate and by no means a contemptible character. Since that time I have had others made, which I have improved upon, and which I am pleased to say is working for me now, pumping water, &c., and without the least trouble or attention, except to put on the position by the large model at seven o'clock. But as I once erred greatly when I thought it might be improved, it has long since been taken by, and another one is now building. The old one, however, is still in existence."

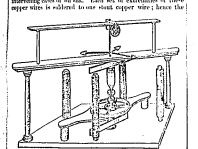

Fig. 17

From "Annals of Electricity," April, 1837, Vol. I., page 278:—

"In the first number of these 'Annals,' I have described an electro-magnetic engine, by means of which pieces of machinery are put in motion. I have now to announce that I have succeeded in propelling a boat, and also a locomotive carriage, by the power of electro-magnetism. The particulars of their construction will be communicated as soon as their present rude state is sufficiently corrected for their appearance in public.

"W. S."

Vols. II. and III. of the "Annals" have been enriched, but no further notice appears of the electro-magnetic locomotive.

Advertisements intended for insertion in the current week's issue must be delivered not later than 4 p.m. on Thursday. The charge for Advertisements is 6d. a line for the first insertion, and 4d. for every subsequent insertion for each additional line. The line contains eight words, and the average length of words is taken. Displayed advertisements, wherever their insertion cannot be guaranteed. Terms for displayed advertisements on the wrapper will be forwarded on application. Orders for, and alterations in, advertisements will be received addressed to the publishing engineering, but absolute regularity cannot be guaranteed.

SUBSCRIPTION, HOME AND FOREIGN.

The price of ENGINEERING to annual subscribers in the United Kingdom, including postage, is £1 16s. per annum, payable in advance. If credit be taken, the charge is £1 18s. The advertising rates payable in advance. Three being two double-numbered parts, the subscription for a year is £1 16s. Subscribers should address to the Secretary of the Publishing Company, with postage-stamps enclosed.

Subscribers will receive the Numbers regularly on the day of publication. Early copies of ENGINEERING will always be printed on thin paper. Foreign subscribers desirous of having their paper copies sent by the Mail, instead of by Parcels Post, can be supplied at the undermentioned rates.

The rates for subscriptions to ENGINEERING from abroad are:—

If sent by Mail to Austria, Belgium, Denmark, Egypt, France, Germany, Holland, Italy, Portugal, Russia, Spain, Sweden, Switzerland, Turkey, United States of America, Australia, Victoria, Italy, Luxemburg, Malta, Mediterranean Islands, Netherlands, Newfoundland, New Zealand, Norway, Prussia, Queensland, Russia, Spain, Sweden, Switzerland, Tahiti, Turkey, United States of America, Victoria, and West Indies	£2 0s. 0d.
If sent by Mail to Canada, China, Japan, Straits Settlements, Ceylon, Japan, and the Hawaiian Islands. Thick paper copies	£2 8s. 0d.

All accounts are payable to the publisher, Mr. CHARLES HUBERT, 28 and 29, Bedford-street. Cheques should be crossed "Union Bank, Charing Cross Branch," Post Office Orders to be made payable at the Strand Office.

Foreign Subscribers, especially those requiring their subscription, are particularly requested to advise the Publisher of the cessation of the Post Office Order, and the exact amount for which it is made payable. If this precaution is omitted, some difficulty is sure to occur in securing the same at the Office.

Offices for Publication and Advertisements, Nos. 28 and 29, Bedford-street, Strand.

TELEGRAPHIC ADDRESS—ENG. LONDON.

ENGINEERING is registered for transmission abroad.

READING CASES.—Reading cases for containing twenty-six numbers of ENGINEERING can be had at the publishing office, 28 and 29, Bedford-street, Strand. Price 2s. each.

AMERICAN SUBSCRIBERS.

We beg to announce that we have appointed Mr. Leon Smith, 31, Pine-street, New York, our agent in the United States. Subscribers to ENGINEERING in the United States will in future be payable to Mr. Leon Smith in New York, and not to the publishing office in London. We will afford full information as to terms, &c., on application.

The Publisher begs to call the attention of Subscribers to the Supplement Sheet of Advertisements presented with the present number of the ENGINEERING.

The Publisher desires to draw the attention of Manufacturers and Inventors to the Premiums offered by the ENGINEERING *and* ENGINEER *Trust established for the new effects of the Patents Act. This means are kept for the benefit of inventors, free of the principal Patents Agents, and the Premiums will be awarded by a Committee of the Institution of Mechanical Engineers, and by the Council of the Institute of Civil Engineers, for the best specification and drawings for the purpose of distribution. A classified arrangement of the various advertisements will be published in the* ENGINEER *and* ENGINEERING *every week, and the Publisher will be glad to receive advertisements for insertion in one or both of these publications, at the following rates:—*

Without their catalogues and circulars, which will be indexed and placed under the several classes of trades.

NOTICE OF MEETING.

THE INSTITUTION OF CIVIL ENGINEERS.—Tuesday, March 14th, at 8 p.m. Papers to be read and discussed: "The Design and Construction of Harbours," by Mr. Vernon Harcourt; and "On the Stability of Structures against the Wind," by John Dunbar.

ENGINEERING.

FRIDAY, MARCH 10, 1882.

THE LIGHTNING ROD CONFERENCE.

THE devastation produced by lightning is fortunately not so considerable in England as in many other countries, and this may account for the fact that no rules have ever been drawn up to guide the general public in the erection of lightning conductors—except by private individuals. In France, however, a Commission was appointed by Government on the Academy were requested by Government on several occasions to draw up such rules, and the practice in France is consequently very much more uniform than in this country. This want being felt, the Meteorological Society issued invitations in May, 1878, to the Royal Institute of British Architects, to the Physical Society, and to the Society of Telegraph Engineers, and delegates were chosen by each society to confer on the drawing up a report on the subject. Had the matter been taken up by Government it is probable that the Royal Society would have been asked to report; but inasmuch as there was no less than seven Fellows of thisociety on the Conference it may be conceded that the report almost carries upon it the stamp of our great scientific society.

That confuse to a feeling of disappointment in perusing the report, which occupies only nineteen pages of large letter-press, which contains several suggestions of a doubtful character, without giving any reasons for them, and which omits many matters of scientific interest, which were certainly to be expected from so distinguished a Conference. The principal labours and the greatest success lie in the appendices, which occupy 200 pages of closely printed matter, and which give in a condensed form a vast amount of historical information on the subject. The members of the Conference divided this labour, and a most valuable level of reference is the result. The small advance in the knowledge of the lightning discharges makes it the impossibility of carrying out experiments except with electricity of a much lower potential. Authentic history is therefore of the greatest importance, and all records written by engineers and careful observers are worthy of the utmost value. The Appendices of the Conference enable the student to easily get at any desired information, and any further investigation is assisted by the excellent catalogue of works upon lightning conductors in Appendix G.

The report recommends that each terminal rod should be provided with a platinum point, the central point being a few inches higher than the others, and fixed by the opinion of Mr. Preece, Appendix B, that "each conductor should end in one platinum point," and that "there is no disadvantage whatever in multiplying these points," as it is understood. The report next recommends copper as the material for a conductor although giving a comparison with iron and steel much in favour of the latter metal. As regards the size of it is considered a section of 0.1 of a square inch inch for copper and of 0.64 of a square inch for iron are recommended. Attention is called to the shape of a conductor, and the desirability of its being free from any joints and the cleaning of the foot of the conductor to protect it from the thief, the nut being there is shown in the sections. The references to the attachment of a conductor to a building, and it is stated that it will not compress the rod but that it shall hold it firmly, and yet shall allow for the expansion of the conductor. A screw section to a gas main is not only permitted when other lightning rod is advocated as an efficient arrangement at all times, although an accident in Hatfield, N.S., is mentioned in which the Provincial buildings narrowly escaped destruction by fire occasioned by a lightning rod being struck which had been in use for a time in this way. We also note that in a rocky soil dry situation it is recommended that only 3 cwt. or 4 cwt. of iron at the foot of the conductor in addition to the ordinary earth system. We understand the 3 cwt. or 4 cwt. of iron will have upon the electric discharge is not explained, although it would be very interesting to learn.

The space protected by a lightning rod receives considerable attention, this being capable of one of the members of the conference. His views, however, are not fully endorsed, and the more guarded opinions quoted from the War Office instructions of 1873 (which are printed in one of the Appendices) are practically adopted. And here we would state that the more recent instructions issued by the War Office last year are not quoted or mentioned, nor are the last Instructions issued by the Admiralty in 1880. The recommendations of the Conference on the height of the upper terminal are illogical, as the matter is first stated to be one which may be left entirely to the option of architects and engineers, whereas in the following sentence the lofty rods often used in France, and the low rods used in England are regarded as "opposite errors."

Concerning the testing of conductors an annual examination both visual and electrical is recommended, and various apparatus are noted. "The simplest and best is effective as regards testing the efficiency of the conductor, but not that of the earth connexion;" but inasmuch as the earth connexion is exactly that which is of complicated, and frequently requires repair, and is also the part which being under ground can only be examined electrically, it would not have been anticipated that a testing apparatus which could be used only for the conductor and not for the earth connexion, would have been recommended as the "best," although it might easily be "simplest." This apparatus is made after designs which were furnished by Mr. Preece, who saw a similar arrangement in France.

The Conference recommends that all masses of metal in a building (church bells in a well-protected spire excepted, reason not stated), whether internal or external, should be connected to each other and to a conductor, or to the earth. Clerk-Maxwell, who followed up theoretically by such beautiful mathematical processes as many of the discoveries due to the experimental researches of Faraday, considered that masses of metal should be treated differently according to their position; internal masses being kept apart from the system of conductors, but the external masses being connected thereto.

The report concludes with the code of rules which seem to err on the side of brevity; indeed some details of importance are omitted altogether. For instance, in the case of large buildings with flat roofs the spacing of the points and of the conductors, as well as the number and the less positions of earth connexions, are not mentioned, nor whether surface as well as deep earth connexions are to be used. It is recommended in the instructions drawn up by the French Academy of Science that "the rules appear to be drawn up without much care; for instance, where it is stated that "the lower end of a conductor should be buried in permanently damp soil," and that it adds "hence proximity to drains is desirable." We were always under the impression that drains produce dryness in soils. Again, in the same rule we find, "a strip of copper tape may be laid from the bottom of the rod to the nearest gas or water main, not secretly to a lead pipe." The use of the word secretly is probably intended as no easy connexion to a soil metal pipe is deprecated universally in the report.

The line of reasoning which appears in some of the rules does not carry conviction. Thus, in the rule about "collectors" it is stated that "undoubted instances occur in the explosion of fire-damp in collieries through sparks from atmospheric electricity being led into the mine by the wire ropes of the shafts and the iron rails of the galleries. The same, the lead gear of all shafts should be protected by proper lightning conductors." As the writer knows, however, is not necessarily good but in the mine, it would, perhaps, be preferable to "earth" the lead gear by a wire down the shaft, the iron rails of the galleries being connected to the same, and earth by means of the bank and at the various seams, and at the bottom of the pit. At all events, some reasons should be given for the belief that protecting the head gear with a proper lightning conductor—if "earthing" the conductor as laid down in the rule for "earth connexion" in the previous paragraph, would avail the evil. The head gear, the winding engines, and the boilers are, we believe, already afford a suitable system of "earthing" which would appear to require no special lightning conductor.

It is most unfortunate that the rules and the report have not been drawn up in a fuller and more convincing manner, as something of the kind of unquestioned authority was still we are compelled to think, still is much required.

THE TRIDANTEPEC SHIP RAILWAY.

In our issue of the 2nd December last we gave a description of the proposed Tehuantepec Railway, by which Captain J. B. Eads, the celebrated American engineer, undertakes to transport laden ships up to a gross weight of 6000 tons, fully laden ships up to 4 fathoms. The plan meets across the American Isthmus, and is, as against with considerable support in America, as against the rival canal schemes of Panama and Nicaragua, on account of its commercial advantages in requiring much less money and time for construction, and also because commercially, and from a military point of view, it is much more favourable to American interests. Tehuantepec is 1250 miles nearer to the North American coast than the Isthmus of Panama, and this additional distance would have to be gone over by a vessel sailing from any of the

SELF-REGULATING DYNAMO MACHINES.—I.

By W. B. ESSON.

IN lighting by incandescence where all the lamps are arranged in parallel circuits, and where in consequence of such arrangement the resistance of the circuit is approximately in inverse proportion to the number of lamps alight, it becomes a matter of great importance to regulate the difference of potential of the system, so that the brightness of each group of lamps is practically independent of the others. To fulfil this condition perfectly, the difference of potential between the positive and negative mains ought to be uniform at every point in the system, and this difference of potential ought to be independent of the number of lamps alight. It is very easy to arrange the leading and returning mains in such a way as to make the difference of potential for each group of lamps uniform when the whole or any particular number of lamps are supplied with current; but by no practicable method of arranging the leading wires yet devised have we been able to obtain constancy, and necessarily any increase or decrease in the particular number of lamps alight must affect to a certain extent the brightness of the whole. The difficulty is introduced on account of the leading wires having a certain resistance, and since this resistance is constant, while the current is a variable, depending on the number of lamps alight, it follows that the E.M.F. expended in the leads, and that available for the lamps are also variables, depending on the number of lamps alight. In the absence of any method of arranging leads for incandescence lighting so that the difference of potential shall be constant at all points for every current passing into the system, it appears that the best plan to adopt is that of keeping the potential constant at the point where the mains are supplied, and to proportion the area of the mains so that the variation which can be produced at any point in the system by the greatest variation in the number of lamps lighted shall not be excessive. A simple calculation enables this to be done readily.

Various methods other than that we are about to consider have been devised from time to time, for the purpose of maintaining a constant difference of potentials at the terminals of the dynamo; the best known being that employed by Edison, which consists in introducing a resistance into the field-magnet circuit of his shunt machines; this resistance being increased as the lamps are diminished, and diminished as the lamps are increased. But this method, although it may answer well enough in practice, depends upon the vigilance of an attendant, who is supposed to introduce the resistance at the right moment, and it is open to the further objection that the very movement which we wish to prevent—namely, the increase in the difference of potentials must take place before the attendant becomes aware of the necessity for acting.

To maintain a constant difference of potential at the terminals of the machine, self-regulating dynamos have been devised which, as implied by their name, electrically adjust themselves, and generate a current which may vary within wide limits to suit circumstances, while the potential remains approximately constant. These dynamos are designed to run at a constant speed, although in some cases a variation of five per cent. is necessary to produce the required regulation, and in consequence of this constancy of uniform speed, in which, be it remembered, the great advantage of the self-regulating dynamo lies, the condition of constant potential is made to depend upon the efficiency of steam-engine governors, which have been brought to a high degree of perfection.

A self-regulating dynamo partakes partly of the character of a magneto machine, and partly of the nature of a series machine. It has wound on its field magnets two coils, one of which having few turns through it an approximately constant current, produces a constant excitation of the field magnets, which is the condition for a magneto machine, the other causing an excitation of the magnets approximately proportional to the current which is the condition for a series machine.

We must carefully distinguish between a constant difference of potential at the terminals of the dynamo and a constant E.M.F. Necessarily the E.M.F. must increase as the current increases, on account of the increased E.M.F. required to send the additional current through the armature and series coil. The connections of a self-regulating dynamo are shown in Fig. 1. A is the armature of the machine; S the series coil on the field magnets through which all the current generated by the dynamo must flow; s a high resistance shunt coil, also on the field magnets shunted from the terminals T and T. By hypothesis the difference of potential between T and T, is constant, therefore the current through s is constant, and the strength of field due to the shunt coil is constant. The series coil S, and the armature taken together, constitute a series machine, and the strength of field added to the magnets by the former is approximately proportional to the current. The shunt coil and the armature taken together constitute a magneto machine, and the relation between the current and E.M.F. in such a machine we have now to determine.

It is frequently assumed that the difference of potential at the brushes of a magneto or separately excited dynamo, when a current C is flowing, is simply $E - Cr$, where R is the difference of potential at the brushes when the machine is running on open circuit, and r is the resistance of the armature. The difference of potential is always less than this formula would show, and there are other causes besides the resistance of the armature to which the fall of potential must partly be attributed, which, moreover, are of great importance in this relation. We have to consider

(a) The reaction of the armature on the field magnets.
(b) The resistance of the armature.
(c) The effect of self-induction in the armature coils.

When a current flows through the armature coils in a dynamo, the armature itself becomes a magnet and creates a magnetic field, which opposes the stronger field created by the field magnets. Since the E.M.F. of a dynamo depends not simply on the strength of the field produced by the magnets, but on the strength of the resultant field produced by the magnets and armature combined, the E.M.F. must be reduced when a current flows through the armature, and if the magnetic moment of the armature is small, compared with that of the field magnets, as should always be the case in a well-designed machine, the reduction of E.M.F. due to this current flowing through the armature will be approximately proportional to the current. If, then, E is the E.M.F. of a separately excited dynamo when running on open circuit, when a current C flows through the armature, the E.M.F. becomes $E - C\phi$, where ϕ is a constant depending on the construction of the machine.

Of this quantity, $E - C\phi$, a part $= Cr$ is expended in sending the current through the armature, the latter having a resistance of r, to obtain the difference of potential at the brushes, this part, which is not available for external work, must be deducted from the E.M.F. of the machine, and the fall of potential at the brushes, due to the reaction of the armature on the magnets, and the resistance of the former consequently becomes

$$C(\phi + r).$$

If E be, as formerly, the difference of potential at the brushes when the machine is running on open circuit, the potential, now that a current C flows, is

$$E - C(\phi + r).$$

But there is still another reduction to be made for the potential at the brushes, due to the self-induction of the rotating armature. If we have two adjacent coils, a and b, lying parallel to each other, we know that if a current is suddenly started in a, a current in inverse direction is momentarily induced in b, this latter current depending upon what is termed the mutual induction of the

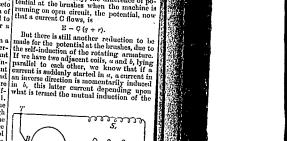

Fig 1.

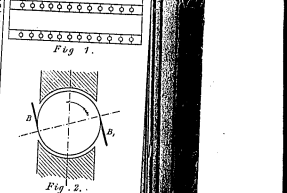

Fig 2.

coils. But if we have a single coil and start a current in it, we find that the different turns of which this coil is made up act upon each other, in the same way as the current started in the coil a acted upon the coil b. In the case of the two coils the induced current in b flowed in a direction such as to oppose or retard the current in a, and in some way the current in each turn of the single coil induces an opposing E.M.F. in the adjacent turns, and the current, in consequence of this retardation, does not at once attain its full strength. This opposing E.M.F. is said to be due to *self-induction*. Let us see how it affects the working of a dynamo machine. *Fig. 2* represents the armature and field-magnets of a dynamo, the brushes being at B and B, and the machine rotating in the direction of the arrow. *Now* in all the coils on the top half of the armature between B and B, the current flows in an opposite direction to

The English Mechanic

AND WORLD OF SCIENCE AND ART.

SELF-REGULATING DYNAMO MACHINES.—II.

By W. B. Esson.

(Continued from p. 262.)

WHEN the home circuit is open the shunt wire has to supply an excitation to the field-magnets such that the e.m.f. at the terminals of the machine T and T, when running at its proper speed, shall be that required for the effective lighting of the lamps, and, as stated in our last article, this e.m.f. is by the combined effect of the shunt and series coils to be kept constant for all values of the current up to the maximum for which the machine is designed.

Given, then, the carcase of a machine, the armature of which is wound with a certain number of convolutions, we have to obtain a particular result from the shunt wire, and since this is quite independent of the series wire, there is no necessity, for the present, to trouble ourselves about that part of the machine. Looking at the diagram (Fig. 1), it will be

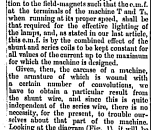

Fig. 1.

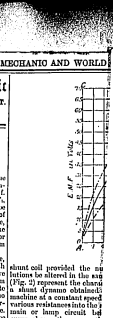
seen that we have a closed circuit through the armature A, series coil B, and shunt coil S', the lamp circuit being open. For the purpose of simplifying matters we shall assume that in consequence of the high resistance of the shunt coil as compared with the combined resistance of the armature and series wire, the whole of the E.M.F. of the machine appears at the terminals T and T'. We shall also neglect the increased resistance of the armature due to self-induction, since the current flowing is very small.

The resistance of the shunt wire ought to be as large as possible; the higher its resist-



shunt coil provided the number of turns be altered in the same (Fig. 2) represent the characteristic shunt dynamo obtained by machine at a constant speed with various resistances into the main or lamp circuit before shown the connections. The e.m.f. and the current flowing through the armature the connection between the in the magnet coils, and the the magnets are thereby ances along A B represent amperes, and vertical distances volts. With reference to this description, while between the e.m.f. and one a machine in which the and armature form one M. Depres and others have an increase or reduction the ordinates will give the a machine in which the armature pressed or diminished in the the same way it has to the lengths of the abscissæ correspond to the number of magnets of a new machine machine appears at the terminals T and T'. We shall also neglect the increased resistance of the armature due to self-induction, since the current flowing is very small.

The resistance of the shunt wire ought to be as large as possible; the higher its resist-

former to the new speed, drawn to scale, and the required to obtain by re-constructing or describing a sufficient solution for the number of sistance of the shunt wire self-regulating machine will give to construct. The number of magnets of wrought-iron, long by dia. dia., and ture 600 convolutions of dia., which would carry heating, a current of 18 amp

As will have been gathered from the resistance of the depend to a great extent on the machine. The higher higher may the resistance of be made, and the greater of course the efficiency. In dynamos, generally speaking, of the shunt is from 200 to of the armature.

In the present article, we how, by a method of consistance and the number of shunt wire may be approxi from experiments made with machine, which has accessible magnets, a large number of, and requires a small exciting machine, however, may be in which case its field magnets excited by another machine the brushes for each different must being measured, and the down in a curve similar to D this experiment there will be ing through the armature (the required for the voltameter) shown on the curve may be ar when, as in ordinary working flowing through the shunt and the armature), but if this small, as it usually will be, the introduce may be neglected. out such a curve, the number on the magnets and the re fine wire coils of the series may be determined. An illustrated. Suppose we have a which under ordinary work amperes and 450 volts at 1,200 per minute; further assume its field magnets 2,200 and on its armature 1,1 tions; keeping the speed 1,500, we plot out the cu the connection between the exciting current, and select some curve where the magnets are saturated, to represent the dy it is desired to saturate the m shunt coil. Let this particul cate 250 volts, with an excite 2·3 amperes. But we require difference lamps 50 volts, a on the armature will therefore 1500 + 50 = 200, the ares being, as compared with 250 areas, in the ratio of 200 : 250.

The ampère-turns on the field-magnets must be proportional to the ohms 250 volts were 2·3 × 2·3 = 5·29 ohms, and we know that with the resistance of 5·29 ohms the number of convolutions on the armature

cells are very conveniently shaped for stacking in any odd corner, and are preferably of wood with a lining of sheet-copper. The oxide of copper is bought in a hydrated form from the smelters, but is readily reoxidised in a small coal; caustic soda is employed instead of potash, and the purified chloride is oxide of zinc, a white pigment, which is fit is stated, sells at £20 per ton. This is zinc to construct. The metal being recrystallised all the materials are recovered available again, except the metallic zinc, which now appears in increased bulk as an oxide. One ton of zinc yields a ton and a quarter of the oxide, so that deducting the cost of the zinc from the price obtained for the oxide we have, on paper, a cell which yields electricity for nothing. It is obvious that, in practice, there will be the cost of collecting and revivifying the materials and of preparing them for market; but, looking to the convenient manner in which the battery can be arranged, the absence of any unpleasant gases, the duration of the action, and the fact that there is no waste while the current is not being utilised, it will be understood that there is a very promising future for the cells of copper oxide, or, as we have called, the "Domestic Primary Battery." According to Ferguson's offices a battery of 45 cells gives 40 volts and 16 amperes, works for a month without attention, and occupies very little space.

BREMAN'S IMPROVEMENTS IN ELECTRIC CIRCUITS.

IT is very well known to electricians that in electric light installations where the main conductors are of great length there is considerable reduction of potential at the ends further from the generators; for that reason lamps of different qualities are employed in parts of the circuit, and the whole is balanced in a tolerably effective manner. Mr. J. R. Breman, of Early Grant-road, W., has recently patented a method of distributing electric energy, whereby the distribution of electricity, in which he uses balancing resistances and two or more generators at parts of the circuit, the batteries or coils of batteries being so arranged or constructed as to produce currents of practically equal or nearly equal electromotive force and equal or nearly equal volume of quantity.

It is not in all cases necessary that the electromotive force of each of the batteries should be equal or nearly equal, although this would be generally more economical or convenient. For instance, there may be three batteries, two dynamos and 12 lamps; the current producing in each dynamo being, say, 10 amperes, the resistance of each lamp being 2 ohms, therefore the total electromotive force required to force the 10 amperes through those lamps, assuming that the leads and batteries are without resistance, is 12 × 2 × 10 = 240 volts. And if dynamo A produces 250 volts, dynamo B 220 volts, and dynamo C 260 volts, we have the necessary electromotive forces for doing the work; or each dynamo would produce an electromotive force of 240·3 volts, when the same result would be obtained.

Neither is it in all cases necessary to the invention that the current produced by the batteries should be approximately equally equal. For instance, a dynamo B fall of pressure being separately excited and their fields kept constant) produces, say, 20 amperes and dynamo A and C only 10 amperes each, then the electromotive force of dynamo B must be of such a higher potential as to overcome the resistance of batteries A and C to the extra 10 amperes passing through them, and the armatures A and C must have conductors of sufficient current-carrying capacity to allow the passage of the greater current with safety.

The + conductor from the first battery is taken by a convenient route towards the second battery, and alongside and parallel to the − conductor of the second battery, and the + conductor of the second battery is taken by a convenient route towards the third battery, and alongside and parallel to the − conductor of the third battery, and the + conductor of the third battery is carried in the same manner to the next, and this arrangement is continued until the + conductor of the last battery proceeds towards the first battery and alongside and parallel to the — conductor of the first battery.

When the conductors are in parallel, the external circuit of adjacent or following batteries is completed by interposing resistances, automatic or otherwise, lamps, motors, or any other means of translating device or devices, alone or in conjunction with resistances, automatic or otherwise, either in multiple arc or multiple series, or any convenient combination between the + conductor of the one battery and the − conductor of the following battery.

By means of these balancing resistances the electromotive force on all the parallels may be kept equal, notwithstanding the removal from any parallel of one or more translating devices, lamps, for example.

It is obvious that if all resistances, lamps, motors, or other translating devices are cut off from the circuit, because any two contiguous batteries there will be a short circuit. In this case the circuit can be completed by introducing suitable balancing resistances of the proper current-carrying capacity. The circuit can be completed by "earth," or by the conductors or conductors, and then by any suitable means keep the work required to be produced by the batteries at the proper point.

The purpose of the balancing resistances is to transmit at all times the same amount of current shall be circulating in the conductors, however many or few translating devices may be in the circuit.

Any suitable balancing resistances may be employed, and the work done in these balancing resistances may be used, when practicable, in forming or charging secondary batteries, in electrolysing, in the decomposition of chemicals, or in the production of any other useful effect, according to the locality where the batteries may be situated.

As the invention can be applied in a variety of ways to lighting and all work requiring the transmission of current to a distance, it is difficult to give Mr. Breman's claim, which is:—

The arrangement of appliances for distributing and translating electricity by means of suitable and convenient batteries in series, the circuits between them being closed by the interposition between the positive and negative conductors, or positive and negative poles, of adjacent batteries of suitable and convenient resistance, alone or in combination with suitable and convenient translating devices; the translating devices being either alone or in combination with resistances, and being either in series, series multiple, multiple arc, multiple series, or any other convenient combination.

a series of earthquake shocks. As to the cause of earthquakes, we can do little more than conjecture. It is easy to understand that where forces so tremendous as those which recently destroyed Krakatoa are at work, and especially when pent up, they may give rise to upheavals and subsidences of the surface over many hundreds of square miles; but the actual nature of the forces, and the conditions in which they exist, is beyond research. It may be that water in the spheroidal state suddenly flashes into steam, and finding an inadequate vent forces up the superficial crust of the earth; or it may be that steam is suddenly condensed, and the roofs of gigantic cavities fall in; or again, it may be the sudden snap of deep-seated rocks, no longer able to resist a prolonged and intense strain. Of earthquakes proper (as distinguished from the effects produced by volcanic eruptions), especially when they extend over large areas, there is much reason to suppose that they are caused by the ruption of rocks forming what may be termed the supports of the earth's crust. Assuming that the earth has a fluid interior, which is slowly cooling and contracting, it follows that the crust will crack, and, falling in, may produce volcanic eruptions, which, in turn, by the shock of explosion, may start cracks which produce earthquakes. These are broken to learn what facts or what arguments are brought to bear on these questions may be referred to Mallet's papers in the British Association reports for 1847 and subsequent years; to the *Journal* of the Geological Society, and to the numerous special works dealing with the subject, including the "Physics of the Earth's Crust," by the Rev. O. Fisher, which we reviewed in Vol. XXXIV., p. 502, and the standard textbooks of geology.

THE DYNAMO: HOW MADE AND HOW USED.—XVIII.*

By Silvanus P. Bottone.

140. TWO binding screws are now to be inserted into the base-board, to which the wires proceeding from the limbs of field magnet must be clamped. These should be placed about 1½in. from the side of each limb, the wires proceeding therefrom being denuded of their covering and amalgamated at the extremities where they are clamped to the binding screws. These binding screws are also those connected

Fig. 36.

with the brushes; should, for the convenience of being able to couple up at once at the same time, two or more wires, be of the pattern shown at Fig. 36, in which case the extremities of the field-magnets may be also formed into rings, as shown at Fig. 36a, and either clamped down to the base-board by passing the long screw *a* (Fig. 36) into the ring, or, the nut *a* having been removed previous, the ring may be slipped over the screw *b*, and then clamped by the nut *a*.

Connection is now to be made between the binding screw attached to the current-sending or positive brush (the one which we have marked with a paper label), and the binding screw coupled to the wire, starting from the inside of the limb of the field-magnet (see Fig. 25a) by means of a short length of No. 16 copper wire, well cleaned, bent into rings at the ends, and clamped down as before directed.

141. All the instructions have been carefully carried out, more especially those contained in the last six paragraphs, we shall find that on rotating the flywheel a powerful current will flow between the two remaining binding screws—viz., the one connected with the outside wire of

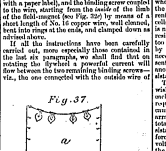


Fig. 37.

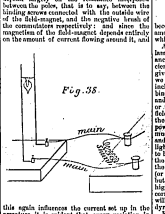

Fig. 38.

the field-magnets, and the other with the negative brush of the commutator, a current which will be sufficient to heat to bright redness 4ft. to 6ft. of No. 22 platinum wire, or to light four incandescent lamps, arranged in parallel arc.

The current actually flowing through the circuit (the number of ampères) will naturally depend largely on the resistance interposed between the poles, that is to say, between the binding screws connected with the outside wire of the field-magnet, and the negative brush of the commutators respectively; and since the magnetism of the field-magnet depends entirely on the amount of current flowing around it, and

Fig. 39.

this again influences the current set up in the armature, it is evident that every variation in the resistance of the interpolar or outside circuit, will produce a corresponding variation in the current, if the dynamo be connected up as above described; and that a very much larger current will traverse the circuit when the resistance is small, than when the resistance is great. When the machine is doing its best work, that is to say, when the resistance of the interpolar circuit is equal to the internal resistance of the machine, the current is equal to 2 divided by 3 or two-thirds of the current it would give were there no resistance. Sometimes it is necessary to send the current through a greater resistance; in this case, in order to make sure that we get the maximum effect of the field-magnets to be thoroughly magnetised, we should first connect the two ends of the field-magnet coils together by a piece of thick copper wire, and then, when we are sure that the field-magnets are thoroughly magnetised, remove the wire, and connect the coils up to the circuit, if

THE EDISON-HOPKINSON DYNAMO.

We have received from Messrs. Mather and Platt, of Salford, the following account of a prolonged and practical trial of an Edison-Hopkinson dynamo constructed by them and designed to give a current of 250 ampères with an electromotive force of 55 volts.

Description of Machine.—The dynamo is of the latest Edison-Hopkinson type with a short armature. The exterior dimensions are, length, 56 in.; breadth, 36 in.; and height, 40 in.; and the net weight of the machine complete is 32 cwt.

The commutator is of copper with mica insulation, and has 48 bars; and is provided with double brushes independently adjustable. The magnets are shunt-wound.

	Ohms.
The magnet resistance is	7.84
The armature resistance is	0.068

The dynamo is designed for a continuous load of 250 ampères, and 55 volts, and is run at a speed of 900 revolutions per minute.

The efficiency of the machine is deduced from the following figures:

	Watts.	Horse-Power.
Total electrical power developed	= 16,216	= 21.74
Loss in magnets	= 691	= 0.51
,, armature	= 720	= 0.96
Power available in outer circuit when run as in test ...	= 15,025	= 20.28

Hence,

	Per cent.
Electrical efficiency	= 93
Loss in magnets.	= 3.4
,, armature	= 4.6

The following are particulars of the test to which this machine has been subjected:

The dynamo was arranged for driving by an ordinary strap from a double-cylinder engine made by Mather and Platt, and carried on slide rails to admit of the belt being tightened if required. One of Sir William Thomson's graduated potential galvanometers was permanently coupled to the machine to give a continuous indication of the electromotive force between the terminals, and arrangements were made for measuring the current by means of a current galvanometer also of Sir William Thomson's graduated type.

The temperatures of the bearings were measured throughout the test by means of thermometers placed in mercury cups attached to the bearings, and a continuous record was kept of the temperature of the room.

The speed was indicated by a tachometer attached to the engine, and the revolutions of the dynamo counted from time to time with a counter.

The load was maintained constant throughout the test, as nearly as possible at 250 ampères, and 55 volts, measured at the terminals. This is ten per cent. above the normal load for which the machine is intended.

The machine was started on December 30th, and run for five hours, when the temperatures were taken as follows:

Room, 17 deg. C.; pulley bearing, 35 deg. C.; commutator bearing, 36 deg. C.; magnets, 35 deg. C.; armature, 76 deg. C.; commutator, 70 deg. C.

At the end of twelve hours' run the temperatures were again taken:

Room, 20 deg. C.; pulley bearing, 36 deg. C.; commutator bearing, 36 deg. C.; magnets, 35 deg. C.; armature, 81 deg. C.; commutator, 75 deg. C.

Again at the end of twenty-four hours the temperatures were: Room, 15 deg. C.; pulley bearing, 30 deg. C.; commutator bearing, 29 deg. C.; magnets, 31 deg. C.; armature, 76 deg. C.; commutator, 74 deg. Showing that at the end of twelve hours the maximum temperatures had been reached in all parts of the machine. Subsequently, throughout the entire run of three weeks' duration, the temperatures did not vary more than was accounted for by variations in the temperature of the room.

The speed maintained throughout the run varied from 910 to 925 revolutions, with the full load, and the armature and magnets warm.

The machine was run continuously, stopping ten minutes daily to read the temperatures of the armature and commutator, and for Sunday, until January 6th, when it was stopped in order to take out the armature and have it examined to determine if there were any sign of charring or deterioration in the insulation of the wire; and in order carefully to examine the commutator. The examination was conducted by Mr. Blackburn on behalf of the Edison and Swan United Company, and no change whatever was observable either in the insulation of the wires of the armature or in the commutator.

It was then decided to run the machine absolutely continuously for a fortnight without any break whatever, with the full load of 250 ampères. This test concluded on January 20th.

Throughout the whole of this continuous run for fourteen days there was never the slightest sparking at the commutator, the brushes and magnets remained at a uniform temperature throughout, and the temperature of the commutator at the end of the run was 70 deg. C., practically the same temperature as at the end of twelve hours. One set of brushes were used without change of adjustment for twelve days, and all the end were found to be worn down uniformly ⅛ in.

The commutator was perfectly smooth, and showed no signs of wear or grooving, and the armature had stood the run without the slightest swelling or any sign whatever of change in the insulation.

These tests were undertaken by Mather and Platt at the request of the Edison and Swan Company, in order to show the durability of the Edison-Hopkinson dynamo under a long and continuous strain with a load of 10 per cent. in excess of that for which the machine is sold. The conditions of the test were formulated by Mr. Allright and Mr. Blackburn on behalf of the Edison and Swan Company, and it was superintended by them and their representative, Mr. Crompton, during the entire run.

It proved conclusively that a dynamo of this type may be run continuously without any change in its working parts or deterioration in the insulation of the copper conductors or change in their resistance, and that the wear is exclusively confined to the commutator and copper brushes, and that, with regard to the former, three weeks' run is not sufficient to produce any visible wear, and that the brushes last much longer than is usually supposed, one set being capable of lasting a year on a machine running on an average three hours a day.

Eng'neering - Jan 6 1882

Dynamo-Electric Machinery. By S. P. Thompson, B.A., D.Sc. London: E. and F. N. Spon. 1881.

The appearance of the present volume is caused by the demand for copies of the Cantor Lectures on Dynamo - Electric Machinery, delivered by the author before the Society of Arts in the autumn of 1882. Yet in no sense can the work before us be considered a mere reprint of the lectures, a large amount of matter having been added, to render it a complete manual of existing types of dynamo-electric machinery, those matters having simply an historic interest being very judiciously omitted. The present work is the first in which the theory, the design, and the working of dynamos have received thorough investigation, and we are pleased to see that this is done in a practical way; the mathematical calculations do not include several of the smaller secondary matters at work in a machine, and although much simpler than many of the more complicated formulæ found in other papers, give practically as true results. The volume, although written more especially for students of electro-technics, to whom we can most thoroughly recommend it on account of the comprehensive and practical way in which the subject is treated, will be of service to all practical and theoretical electricians, and the former will find many valuable hints given by the author in discussing the different points of the machines.

In the first chapter, Professor Thompson considers the term dynamo-electric machine and defines it as a "machine for converting energy in the form of dynamical power into energy in the form of electric currents by the operation of setting conductors to rotate in a magnetic field," which is a happily expressed explanation of the action which takes place. In the following chapter the discovery of Faraday that electric currents are generated in conductors by moving them in a magnetic field is discussed, and this leads to the principles on which dynamo-electric machines are constructed, and to their classification into three main groups. These are as follows: 1. Dynamos in which there is rotation of a coil or coils in a uniform field of force, such rotation being effected round an axis in the plane of the coil or one parallel to such an axis, such as the Gramme, Siemens (Alteneck), Edison, Lontin Burgin, Schuckert, &c., machines. 2. Dynamos in which there is translation of coils to different parts of a complex field of varying strength, or of opposite sign (most of these machines, but by no means all, supplying alternating currents), such as the Pixii, Wallace-Farmer, Siemens (alternate), Gordon, Ayrton and Perry, Edison (old), Thomson-Farmer (alternate), Thomson (school dynamo), De Meritens, &c., machines. 3. Dynamos having a conductor rotating so as to produce a continuous increase in the number of lines of force cut, by the device of sliding one part of the conductor on or round the magnet, or on another part of the circuit, such as the Faraday disc, Siemens unipolar, and Crompton machines. The only machine which does not fall within any of these classes is the toothed-armature of Edison, in which the coils are wound to and fro at the ends of a large toothed, instead of being simply rotated on a spindle. The Elphinstone-Vincent and four-pole Schuckert and Gülcher machines are included in the first class, being really compound machines. This classification is far more comprehensive than the old way of dividing machines into continuous or alternating-current, cylindrical, disc-wound (spider, drum), self-regulating, &c., and a complete summary of Professor Thompson's classification will greatly aid the reader in understanding the subsequent chapters of the work and in obtaining a clear grasp of the subject. Chapter III. treats in detail of the different classes of dynamos and their constituent parts under their several headings, the diagrams being exceedingly clear. The reasons for particular forms of structure or arrangement of parts are also given in a clear and precise manner, and some of the faults of existing machines are indicated and will be found worthy of special attention. The succeeding chapter explains, by the aid of curves, the induction of currents in armatures and the distribution of potentials around the collector, and also the mode of investigating these curves. It concludes by a lucid explanation of the Siemens ring, after which the author states that the Gramme pattern of ring armature, so far from being an improvement on the old Pacinotti ring, is distinctly a retrograde step, always supposing that the cost of construction, liability to heating, and other kindred matters, be equal for the two, in which conclusion we thoroughly agree. The reactions in the armature and magnetic field form the subject of Chapter V., and the author attributes the lead which it is necessary to give to the brushes to this cause, and infers that the magnetic moment of the field magnets ought to be very great as compared with that of the armature so as to reduce this lead. To effect this he advises that an unusual quantity of iron of the softest kind should be employed for the field magnet cores. This idea appears latterly to have been acted upon by several prominent makers with good results. He next considers certain effects due to self-induction and to mutual induction, amongst which is the apparent increase of resistance in the armature coils proportional to the speed, which may be diminished by employing more iron in the core and fewer turns of wire. The chapter on the government of dynamos deals with the various methods of exciting the field magnetism, viz., by one of the four simple methods, as in the magneto, separately excited; series and shunt dynamos, respectively; and by various combinations of them for obtaining a constant potential as required. By combining the following arrangements, viz., the series with the separately-excited, the magneto, the shunt, or the shunt to the working circuit only, a constant potential can be obtained at a certain speed, these combinations including Professor Perry's arrangement of introducing a separate magneto or separately-wound dynamo into the circuit of a series dynamo. If a constant current is required the shunt arrangement is combined with the separately-excited magneto, or series arrangement. This chapter concludes with a description of methods of automatic regulation effected by the aid of electro-magnets acting on resistances or on the steam supply of the driving engine, or if a constant current is required by driving the dynamo by a dynamometric governor to maintain a constant torque or turning moment. From these few cursory remarks it will be seen that this part of the work deals thoroughly and efficiently with the whole subject of the government of dynamo-electric generators. Chapters VII., VIII., and IX., containing seventy-six pages, describe the various types of machines under the three classes mentioned above; the machines are fully illustrated and their special points clearly indicated in an impartial manner. In Chapters X. to XV., (inclusive) algebraic expressions are found for the electromotive force, the current and the economic coefficient of the principal types of dynamos, an expression being first found for the average electromotive force induced in a single coil rotating in a uniform magnetic field which leads to the consideration of magneto, separately-excited, series, and shunt dynamos, and finally to the various forms of compound machines derived to give either a constant potential or current. We notice a few printer's errors amongst the formulæ, and also a slight algebraical error, several times repeated, occurring in the latter part of Chapter XV., which, however, does not affect the results arrived at; in giving the critical speed of a dynamo for a constant current, the constant in the formulæ should be a divisor and not a multiplier.

Chapter XVI. deals with alternate current dynamos, the results of which are greatly affected by the retardation of magnetism and the self-induction in the coils. The retardation increases with the speed and affects the ratio between the self-induction and the resistance, and is less if the machine is designed to be driven at a slow speed and the coefficient of self-induction is small compared with the resistance of the circuit. The coefficient of self-induction represents the number of lines of force which the circuit would possess or induce on itself, if the current flowing in it were one absolute unit. These most valuable chapters (X.—XVI.) will undoubtedly prove of special interest to electricians having to design dynamo-electric machinery, for, as above stated, the formulæ are simpler than those hitherto published, and should be within the grasp of the average designer. The geometrical theory of the dynamo is studied by the aid of graphic diagrams, and particularly by the use of "characteristic" curves, which have to the dynamo a very similar relation to that which the indicator diagram bears to the steam engine. The characteristic curve represents the relation existing between the total electromotive force and the current (which vary with the outside resistance), and as, by multiplying the electromotive force by the current, we get the horse-power, it is easy to mark off the horse-power required for each particular case. The curve illustrating the relation between the available or external electromotive force and the current, entitled by the author the "external characteristic" curve, differs slightly from the characteristic curve, is more generally useful for many calculations, and is evidently more readily obtained. These curves indicate, when their scale is known, the horse-power at which the dynamo works, and also at what horse-power it may be worked to the greatest profit, and, though the scale is not known, the form of the curve affords definite information as to the condition of working of the machine. The chapter also gives various examples of the use of these and other curves, which will be found to possess a considerable amount of interest and also of utility.

The succeeding eight chapters treat of dynamo-electric machines considered as motors, or machines for converting the energy of electric currents into energy of mechanical motion. In Chapter XIX., which discusses the theory of electric motors, the author gives Jacobi's law of maximum work of an electric motor supplied with currents from a source of given electromotive force, which is as follows: The maximum work given out by a motor is a maximum when the motor is geared to run at such a speed that the current is reduced to half the strength that it would have if the motor was stopped; *i.e.*, that the back electromotive force of the motor is equal to half the electromotive force of the current supplied to it. The author then deduces from this law—which is often erroneously given in text-books as the law of maximum efficiency—that no motor working at its maximum activity could convert more than 50 per cent. of the electric energy supplied into actual work. It is very interesting to compare this law with Siemens' law of efficiency, which is given later on in this chapter. This law is as follows: The useful work done by the motor is to the electric energy supplied, as the counter electromotive force set up by the rotation of the motor is to the electromotive force supplied to it, and this shows that by letting the motor run so fast that the counter electromotive force is nearly equal to the electromotive force supplied, the efficiency will be nearly equal to unity. Special forms of motors are fully discussed and explained in Chapter XXI., and the succeeding chapter describes several forms of governing gear for motors, including Hopkinson's, Beckmann's, and Ayrton and Perry's. The relation of speed and torque of motors to the current supplied is discussed in the next chapter. Chapter XXIV. treats of the governance of motors by centrifugal, dynamometric, and electric governors, and by the methods of winding the field magnets. Several motor problems are graphically solved in Chapter XXV. The concluding chapter describes the methods of testing dynamos, including the tests of the resistances of the various coils and connections, and of the insulation of the working parts and tons of efficiency under various loads and of electrical output at different speeds. There are six appendices which discuss respectively the measurement of self-induction in a coil; the measurement of mutual induction between two coils; formulæ used for electro-magnets; fundamental equations of dynamo-electric machines and the theory of M. Deubert; the alleged magnetising; and the movement of the neutral point, and will be found well worthy of perusal.

In conclusion we would again commend the present work to all our readers, which will increase the high reputation of its author, and will doubtless long be quoted as an authority on the special subject of which it treats. The work is got up in good style, and is well and sufficiently illustrated throughout.

Engineering - Feb. 4/55

High Tension Current Dynamos.

The danger incurred by the use of very high tension current dynamos, in addition to one of the most serious obstacles to the development of electric lighting from large central stations. A French electrician, M. d'Arsonval, Professor at the College de France, has recently (Jan. 26) communicated a paper to the Academy of Sciences in which he explains how he has been enabled to render the employment of such machines absolutely free from danger. He introduces the subject by the often-repeated remark, that it is not so much the tension of that which is the source of peril, as the counter current, set up at the moment of breaking or making contact. It is on this account that with equal tension, alternating currents are usually less dangerous than those of maximum efficiency—that is, currents of opposite values, succeeding each other suddenly, produce physiological effects vastly more energetic than continuous currents. M. d'Arsonval concludes from this, that a series coil machine giving currents of equal tension and equal strength may be very unequally dangerous, and that even a current that may be dangerous in one circuit need not be so in another. To avoid this risk it is sufficient to prevent the extra current to traverse the body of the experimenter, and to do this it is only necessary to place in connection with the terminals of the dynamo a series of small voltameters with lead plates and acidulated water, in sufficient number that the electromotive force of polarisation may be greater than the electromotive force of the machine. This arrangement is claimed to set up an absolute barrier for the direct current, whilst the extra current passes freely. At the moment when the circuit is broken the extra current traverses the voltameters, and the safety of the experimenter is guaranteed. The efficiency of this method can be very easily tested.

The Engineer Nov. 13, 1885

DRIVING DYNAMO-ELECTRIC MACHINES.

THE paper of which we published an abstract on page 388 rejects an idea which was even more prevalent amongst electricians a year or two ago than it is now; namely, that electricity must be brought into play to control the admission of steam to a steam engine, if sufficient exactness to secure uniformity of speed is to be obtained. The governor of an engine, we are told in the paper referred to, "should be sufficiently sensitive and trustworthy in action to keep the engine within 5 per cent. of its normal speed, with a load varying 10 per cent., and a boiler pressure varying 10 lb. per square inch. No mechanical governor will do this, and consequently great vigilance has to be exercised on the part of the attendant." We have no intention of suggesting that a good and simple electric governor is not at all a desirable thing, but we believe we express the opinion of a good many practical electrical engineers when we say that even if the above statement as to the requirements of a good governor were not only beyond the power of any mechanical governor, and equally beyond the power of any electrical governor, such requirements are wholly unnecessary in practice, and a well-considered installation would never make such a demand upon the governing capacity of any engine. Whether this is so or not, it is quite certain that the inference is that not one of the many installations of different sizes now in successful work is driven by an engine which has the required governing power. There are, however, plenty of engines running that under ordinary conditions of variation of load and boiler pressure are running within less than 5 per cent. of the normal speed. They are not, however, running with loads constantly varying from 100 to 10 and 10 to 100, and inasmuch as no anticipatory governor has yet been devised, it is quite certain that an engine can work within 5 per cent. under such ranges of load. Some seven tests on the power of a good governor and automatic cut-off were put upon one or two of the large engines used at the recent Health Exhibition, when the large strips there used, and transmitting over 300 indicated horse-power, suddenly broke, thus reducing a load of almost 10,000,000 foot-pounds per minute to nothing. The engines did not, however, perceptibly increase their speed; but there is no doubt that if the load had been suddenly put on as taken off, a great change would have been observable. The range of 10 per cent. is not very much less than the whole load, and if nine-tenths of a load is to be taken off and put on again as suddenly, it is quite certain that no governor, electric or otherwise, if actuated by the speed of the engine or a current which is affected by that speed, can cut off and re-admit steam without some loss of time; and a departure of more than 5 per cent. from the normal speed must result, though that departure may have but a brief period of duration. With a slow speed engine making, say, 100 revolutions per minute, a considerable portion of at least two strokes must be made with a steam cut-off and admission determined by the instant load and speed. That is to say, that in the case of a load dropping, say, 90 per cent. just as steam is cut off, that stroke will be performed by that cylinder full of steam; and the velocity must increase, for no governor will act to let the steam out again in such a case. In the half stroke or so thus made the velocity will, as admitted, increase, but the increase will in no case be sufficient to cut off steam nine-tenths earlier than in the previous stroke. The range through which a load may vary with a given range of departure from normal speed of rotation will be a function inversely proportionate to that normal speed, if the range of action of governor or cut-off gear be as great per revolution in the fast engine as in the slow. If the greater part of two strokes, for instance, is required by the engine to accommodate itself to such a large change of load, the high-speed engine running at 500 revolutions per minute will have the advantage, inasmuch as one revolution, instead of being 1 per cent., will only be 0·2 of 1 per cent. The actual difference in the power of the slow and the fast engines to accommodate themselves to such great changes is not, however, anything like this, for the slow engines used for the purpose are fitted usually with a good cut-off gear which will act in as little time as the governing gear or, the fast engine, and consequently the fast engine will depart none per cent. from normal speed than the slow engine, while the inertia of the heavy engine and fly-wheel comes into play and gives it the advantage.

This, however, does not alter the fact that, either as large a range of regulating power is wholly unnecessary, or else that all existing sets of electric lighting plant must be very badly driven. Everyone knows that the latter is not the case, and electrical engineers amongst the rest. A variation in the load of 10 per cent. does not occur frequently, and it would be very injudicious to complicate an engine with governing gear that would vary its speed, and make it run like the engine of a steam steering gear. During the first two or three years of the recent great growth of electric lighting, electricians almost invariably made steady running impossible by one error. They underestimated the power required. No engine can run at a uniform speed with a varying load unless its maximum power is considerably above the maximum load. The first necessity to steady running is power, and this electricians have now learned or are learning. They have at last listened to the engine builders, or perhaps it may be said that a new race of engineers electricians—have come to work in hand or are called in to act in concert with the electrician. Instead of talking of 10 per cent. range of load, we talk only of the range of load resulting from cutting out or putting in a percentage of the lamps in circuit, or of the change of load that takes place gradually at arranged times, then we may say that a mechanical governor will meet the requirements. Portable engines with a common governor, but well above their work, have been called in to work installations, and have done it well; and every large engine builder of reputation has engines running in stock that will show a uniformity in working that cannot be deemed insufficient for any electrical purposes, provided the power is sufficient. The writer of the paper already referred to speaks of an electrical governor working "in perfect synchronism with the load or work to be done, and save the valve in its best position until a change is made either in the load or in the steam pressure." This is simply an impossibility. Perfect synchronism cannot characterise the movements of a driver and a driven if the driven is to be indirectly affected by a change in the speed of the driver. The driven must always follow the driver, and as no electrical governor can only act with difference of current or of potential, it must be indirectly connected to valves and pistons, or otherwise, with the steam cut-off, and hence it is impossible to yet prove that an electrical governor can control an engine better than a good governor and cut-off gear. The author of the paper describes an electric governor which he puts forward as a means of doing that which he says no mechanical governor and no self-regulating or compound dynamo can do. But it may safely be said that none of the practical electrical engineers would think of using the electrical apparatus he has described with the lead idea of either governing an engine or of saving lamps; its action would be less certain and no quicker than a mechanical governor, and an apparatus depending on small friction gear of the kind used, for its action would certainly save no lamps, which would not be safe with a compound dynamo driven by any engine.

Electrical governors might be usefully employed to govern the dynamo-electric machine, but it certain that nothing yet shown will do what a good automatic cut-off gear will not do.

EFFECTS OF HEAT ON THE ENDING QUALITIES OF IRON.

FEW weeks since we noticed the results of a interesting series of experi ndence of temperature on and steel and iron which ha F. Barnaby, the resident A ENGLAND." That gentleman has of tests with samples of low of accentuating the heat or be that is neither cold nor hot sh ding, and is unsafe to work ese are given in a copiously ry of which was kindly s ic by Mr. Barnaby upon sample ufactured by Messrs. C. Cam en and Co., the Butterley Comp ven, of the Milton and Elsecar I many experiments made, Mr. B number which show the general ults obtained. He observes y similar to steel in the fractures are different, for h temperatures shown by him part, fractures nearly wholly count of its homogeneous charac perature shown fractures in the ne of the bars or layers of which ir plates being made from a pile inside up of rious bars according to the weight, size, and ality of the plate required, when the ultimate rivet which occurs, these pieces of gauge ns steel, and only occur when the furnace or ce, &c., from the rusticity of the material, but verter, &c., from the rusticity of the material, but ly set by accident into the mass. It is not taken in n the case of iron, if great heat is not taken in making the piles for rolling, and also care be used in ge, laminations will frequently occur, as proved by nese experiments, Mr. Barnaby endeavoured to ascer- esting the iron at various degrees of temperature, and ain that which is most dangerous, and he is of opinion that at from 700° to 750° F. it is most liable to fail in bending than if bent cold. In his former port it is shown that these different temperatures have the effect of lineally increasing the tensile strength the material, and to show that the iron or steel is ecidifying, which together with the bending, will is considerably stiffened. This, he thinks, will account for the falling off in its bending qualities. He states that he has arrived at these temperatures by the colour of the heated iron as given in scientific erbooks. The report is of a very interesting and in- structive character.

PORTABLE ELECTRIC LIGHT PLANT.

THE interesting on page 336 illustrates a portable electric light plant of a type adopted by the French government for service in the army, more especially for throwing a powerful light upon fortified positions. It also intended as a Field notes. defence. The plant consists of a Gramme gome three-cylinder fleshwood engine, the invention of otor and regulator, a reflector, the invention of Colonel Mangin, of the French army, and a drum for carrying a certain length of conducting wire. The whole is mounted on a four-wheeled carriage, which may be drawn by two horses. The Gramme machine, which is of 3 horse-power, is driven direct from the engine. The electro-magnets are flat and very wide, and the bobbin between them revolves vertically by means of a commutator mounted on the machine, and the changes may be effected instantaneously. When the electro-magnetic parts of the machine are coupled for quantity, with an expenditure of 6 horse-power, the light produced varying from 500 to 1200 Carcel burners, or 5000 candle-power. When coupled for tension, the machine revolves with a velocity of 1200 revolutions per minute, with an expenditure of 8 horse-power,

Tools. For certain purposes it has been found desirable to have a longer or thin; and arrangements are in progress now tank will be accommodate in Hanley, where the

In rating the limestone, it was not necessary to have a great number of experiments, each at a different speed; but usually only three experiments, each at a different speed, 2 feet, and 3 feet per second, were employed, at first. All the intermediate speeds were found by interpolation between these three experiments. The experiments with water at 1 foot, 2, and 3 feet per second, were made accurate to 5 per cent., and the rate curve of this water at the above the method of this water and of water at the the water, the speed, in feet per second, the abscissas represent the speed, in feet per second, the abscissas represent the ordinates the resistance in pounds. The curves of tares of tons. 10 and 15 tons are similar curves, and the ordinates were from the results of Mr. 1 by proportion between the values in the scales for 10 tons and 15 tons. It is unnecessary to explain this similarity any further, as the mathematical considerations which are found on submission will not be entered into here. Any small errors which may have been in the experiments may arise from draughts of air or from the system employed in measuring the water passing the measure. For obvious reasons the deflections of the jet of water from the vertical, as was at first tried in screen by testing the on the end of the rain rod, and making an experiment in the opposite direction after a sufficient interval of time. But it was found that this method, whilst eliminating the error from fortuitous variation of currents, due to draughts or other accidental causes, introduced a fresh error from the fact that there was always a current against the direction of the rod, due to the wake of the water disturbance, and to the wind of the truck in the previous run. To avoid this the practice now has been adopted to experiment in one direction (say from north to south), to return instantly from south to north at the same speed, and then thereby to obliterate as far as possible the effect on the current; then lift the rain rod to the next speed, and travel slowly back from north to south; and then replace the meter to face northwards, and repeat the experiments from south to north. By means of such a pair of experiments, or still better of two pairs, the two error due to currents.

Thanks having been passed to the authors of the paper,

Mr. Marvel and Mr. Tomlinson seconded a vote of thanks to the Institution of Civil Engineers for the use of their rooms. The resolution having been agreed to, the proceedings terminated.

RECENT PROGRESS IN DYNAMO-ELECTRIC MACHINES.*

By Professor SILVANUS P. THOMPSON, B.A., D.Sc., M.S.T.E., University College, Bristol.

(Concluded from page 434.)

The Victoria dynamo is self-regulating, having all the eight field-magnet coils doubly wound, with main circuit coils and shunt coils round each limb. The electrical details of this machine is wonderfully straight. In a 10" machine, with a mean diameter of coil of 14", the following figures were obtained:—Open circuit, 58 volts; 10 amperes, 59·5 volts; 20 amperes, 61 volts; 30 amperes, 62·7 volts; 90 amperes, 39·9 volts; 120 amperes, 20 volts. It will be seen that the current at first practically drops a little; but it is under these circumstances that the engine speed has been observed in practice, so that the cessation of the electrical between the mains is somewhat better than the figures would show. In actual practice, the regulation is marvellous. I have myself opened the circuit of a Victoria dynamo whilst at the very best speed, 1,200 revs., 100 lamps at a distance, I lamp attached to the terminals of the machine, and switching the mains with from two hundred to two thousand lamps were suddenly extinguished. The solitary lamp on the machine did not even flicker, and there was no shake at the brushes. The sparking was so slight as practically to fail whether this machine was on an open or short circuit, or whether it was doing full work. The lead was but very little at all loads. The brushes are of copper gauze, and as a result of this kind. According to measurements made by Mr. Crompton, the resistance of this electrical brush is 0·0000 the figures called, the factor of conversion of this brush is 99·2 per cent. The commercial efficiency is 89·5 per cent. These values assume the B.A. unit of resistance as the true ohm, which we have already probably proved to be not quite so high. Some of these machines are wound for 1,000 volts. The armature of these machines have a spherical activity, slightly lighter, and an efficiency slightly lower, than the Victoria machine. The field-magnet coils are wound with a single wire, and the field-magnet cores have undergone external energy in making the field. These remarks refer, of course, to a comparison between machines of the same size and speed. The Victoria dynamo to work at an equal electromotive force. A larger machine, however, having eight poles, and running at half the speed, and round the ring, has also been constructed by the Anglo-American Company. The armature (fig. 12) has two rings, each 12" in diameter, and 4" wide, and 1" thick. The ring has 192 sections, three layers of wire being wound therefore, between each pole and the adjacent pole of the surrounding ring. An end-on view of the collector is represented with three situated at 90°, 180°, and 270° distance from the first. Only two brushes are required.

Of either singular commentary upon the real superiority of such a machine as the Victoria ring-type of the Edmund type, and of the much-vaunted ring armatures to which we have so often referred, that, although the Victoria machine is a new and improved dynamo, and although the great merit of Edmund, is there is a fair-sizing armature, retaining within a crown of 12 poles. Elaborate illustrations of this machine, and of the details of the Victoria, will be found in the *Revue Industrielle* of January 9, 1884. From this article it appears that the Victoria dynamo of Mr. Gramme for new machines still requires some modification before it can take it quite a successful machine. I measured this dynamo myself, and found it to work quite as well as the multipolar dynamos of Mr. Siemens, and, moreover, nearly mending one another. The pole-pieces are of iron, round, nearly meeting one another. The armature is of Siemens drum form, with a single wire coil sparking at the brushes and leading of the collector segments. The field-magnet coils are of copper ribbon, and are not subdivided. Think of the friction of the brushes upon the collector, and the complication of the latter, and the labour of making and repairing it. I am quite prepared to say that in England we should not think of designing dynamo machines with such a collector. It might suggest itself to us to put two brushes at 90° from each other, with the two coils of field-magnet in circuit with them, and then established at the last Heer Brothers, of Zurich, and has been constructed by the Oerlikon Company. The machine has eight poles in the ring, two compound coils on each pole, and a collector of 128 segments. The speed is 1,000 revolutions, and the output 100 amperes at 100 volts. The present drum is 20" in diameter, and 100 volts. The present drum is 20" in diameter, and 10" long. There is little difference between this machine and the Victoria machine of Gülcher, and the Edmund machine of Schuckert-Mercadier dynamos, which, however, are not multipolar machines. The Victoria machine differs from the Edmund machine in the fact that the latter has a single wire coil on the armature, whilst the Victoria has a ribbon coil. The Victoria machine differs from the Schuckert-Mercadier machine in the fact that the latter has a single wire coil on the armature, whilst the Victoria has a ribbon coil. The Victoria machine differs from the Schuckert-Mercadier machine in the fact that the latter has a single wire coil on the armature, whilst the Victoria has a ribbon coil.

Before leaving the subject of ring-armatures, I should like to refer to a form, recently described by Professor Ayrton and Mr. Perry, of the total length of wire being reduced to the least possible limit, and the resistance to be a small fraction of the total resistance of the armature.

* Read before the Society of Arts, February 20, 1884. We are indebted to the Council of the Society of Arts for the use of the illustrations of the whole resistance of the circuit; and it is possible to reduce the waste due to eddy currents in the armature core without any gain whatever, if, by this spreading, the lines of force in the field. The real reason is, as the following: that the multipolar disc armatures appear to be a step backward, their excellent ventilation; second, their freedom from liability to be injured by the flying of the coils by the tangential inertia (often miscalled centrifugal force) at high speeds; and, third, their low retardation of current to scale; and then replace the meter to face northwards, and repeat the experiments from south to north. By this means of such a pair of experiments, or still better of two pairs, the two error due to currents.

Thanks having been passed to the authors of the paper,

Mr. Marvel and Mr. Tomlinson seconded a vote of thanks to the Institution of Civil Engineers for the use of their rooms. The resolution having been agreed to, the proceedings terminated.

RECENT PROGRESS IN DYNAMO-ELECTRIC MACHINES.*

By Professor SILVANUS P. THOMPSON, B.A., D.Sc., M.S.T.E., University College, Bristol.

(Concluded from page 434.)

The Victoria dynamo is self-regulating, having all the eight field-magnet coils doubly wound, with main circuit coils and shunt coils round each limb. The electrical details of this machine is wonderfully straight. In a 10" machine, with a mean diameter of coil of 14", the following figures were obtained:—Open circuit, 58 volts; 10 amperes, 59·5 volts; 20 amperes, 61 volts; 30 amperes, 62·7 volts; 90 amperes, 39·9 volts; 120 amperes, 20 volts. It will be seen that the current at first practically drops a little; but it is under these circumstances that the engine speed has been observed in practice, so that the cessation of the electrical between the mains is somewhat better than the figures would show. In actual practice, the regulation is marvellous. I have myself opened the circuit of a Victoria dynamo whilst at the very best speed, 1,200 revs., 100 lamps at a distance, 1 lamp attached to the terminals of the machine, and switching the mains with from two hundred to two thousand lamps were suddenly extinguished. The solitary lamp on the machine did not even flicker, and there was no shake at the brushes. The sparking was so slight as practically to fail whether this machine was on an open or short circuit, or whether it was doing full work. The lead was but very little at all loads. The brushes are of copper gauze, and as a result of this kind. According to measurements made by Mr. Crompton, the resistance of this electrical brush is 0·0000 the figures called, the factor of conversion of this brush is 99·2 per cent. The commercial efficiency is 89·5 per cent. These values assume the B.A. unit of resistance as the true ohm, which we have already probably proved to be not quite so high. Some of these machines are wound for 1,000 volts. The armature of these machines have a spherical activity, slightly lighter, and an efficiency slightly lower, than the Victoria machine. The field-magnet coils are wound with a single wire, and the field-magnet cores have undergone external energy in making the field. These remarks refer, of course, to a comparison between machines of the same size and speed. The Victoria dynamo to work at an equal electromotive force. A larger machine, however, having eight poles, and running at half the speed, and round the ring, has also been constructed by the Anglo-American Company. The armature (fig. 12) has two rings, each 12" in diameter, and 4" wide, and 1" thick. The ring has 192 sections, three layers of wire being wound therefore, between each pole and the adjacent pole of the surrounding ring. An end-on view of the collector is represented with three situated at 90°, 180°, and 270° distance from the first. Only two brushes are required.

Of either singular commentary upon the real superiority of such a machine as the Victoria ring-type of the Edmund type, and of the much-vaunted ring armatures to which we have so often referred, that, although the Victoria machine is a new and improved dynamo, and although the great merit of Edmund, is there is a fair-sizing armature, retaining within a crown of 12 poles. Elaborate illustrations of this machine, and of the details of the Victoria, will be found in the *Revue Industrielle* of January 9, 1884. From this article it appears that the Victoria dynamo of Mr. Gramme for new machines still requires some modification before it can take it quite a successful machine. I measured this dynamo myself, and found it to work quite as well as the multipolar dynamos of Mr. Siemens, and, moreover, nearly mending one another. The pole-pieces are of iron, round, nearly meeting one another. The armature is of Siemens drum form, with a single wire coil sparking at the brushes and leading of the collector segments. The field-magnet coils are of copper ribbon, and are not subdivided. Think of the friction of the brushes upon the collector, and the complication of the latter, and the labour of making and repairing it. I am quite prepared to say that in England we should not think of designing dynamo machines with such a collector. It might suggest itself to us to put two brushes at 90° from each other, with the two coils of field-magnet in circuit with them, and then established at the last Heer Brothers, of Zurich, and has been constructed by the Oerlikon Company. The machine has eight poles in the ring, two compound coils on each pole, and a collector of 128 segments. The speed is 1,000 revolutions, and the output 100 amperes at 100 volts. The present drum is 20" in diameter, and 10" long. There is little difference between this machine and the Victoria machine of Gülcher, and the Edmund machine of Schuckert-Mercadier dynamos, which, however, are not multipolar machines. The Victoria machine differs from the Edmund machine in the fact that the latter has a single wire coil on the armature, whilst the Victoria has a ribbon coil. The Victoria machine differs from the Schuckert-Mercadier machine in the fact that the latter has a single wire coil on the armature, whilst the Victoria has a ribbon coil.

Before leaving the subject of ring-armatures, I should like to refer to a form, recently described by Professor Ayrton and Mr. Perry, of the total length of wire being reduced to the least possible limit, and the resistance to be a small fraction of the total resistance of the armature is as follows:

sane weight of rail the railway would carry a greater weight. For agricultural purposes it was a great advantage to have joints, so that there were no loose parts, because with unskilled labour these loose parts were easily lost. He was at present constructing a little railway seventy miles long for conveying wheat and passengers in the Bombay Presidency—a 20-lb. rail with a trough-formed sleeper, which imbedded itself better in the ballast than a elevated sleeper. The gauge was 2 feet 6 inches, and the engineering expenses had been less than one of the road. With such extreme lightness the safest principle was to follow that of the permanent and heavier gauge railways.

Mr. Hartley said he should have been glad if the author of the paper had given a little more data about M. Decauville's cars. The cars were very light, and were not calculated to stand the rough work constantly found upon contractors' lines. He thought the fixed points in portable railways were not very good. Supposing they had to turn off in the middle of a train of waggons with as a fixed point in order to avoid another every truck as it came along to the switch. It was far better to have a moveable switch, and so to diverge the waggons in the proper method.

Mr. Corbett, M.P., said although of course great credit was due to M. Decauville, he thought the greatest credit was due to Mr. Hamilton, who for many years used the narrow gauge railway in transporting iron ore steel from one department to the other at Crewe. His impression was that military men ought to adopt portable railways very much more than they had done. There was a committee sitting at the present time to enquire into the question of transport. The transport in nearly every war had broken down, and he believed that in the last Indian war the transport broke down tremendously. In the discussion in the House with reference to appointing the committee, he pointed out the mistake that the Government had made in the Egyptian war, that three days' provisions for four or five large locomotives, several first, second, and third class carriages and waggons; and when they got to Egypt they had not made the slightest arrangement to take them out of the ships, and not a single locomotive or waggon was landed.

Mr. Cochrane said, with regard to fixed points, it was a well-known fact that the object of these lines was not to attain high speed, and the greatest speed referred to in the paper was one of forty miles an hour. The lines in Tunis, because fixed points were admirably adapted for the purpose.

M. Flateau, in replying on behalf of M. Decauville, who was unable to be present, said that in the case of a line for farming purposes, the sleeper was much shallower than it would be made for heavier earthwork or for a tunnel. He had occasion to conduct an experiment a short time back, in which the line was put down on slanghter ground. The fish plates were not even bolted together; four locomotives and several trucks which were charged 2 tons each, were passed over the line, and although the rails could not find any place where the dish sleeper had given way. With regard to the shoe plates, the experience was that the use was not so very practical; after it had been lying for some time in the ground, it would get rusty and could not be replaced. M. Decauville had adopted several different systems of buffers, and in the case of heavy earthworks a spring buffer was used. As to the turntables, he had assisted at experiments in the transport of guns, and they found that a gun weighing 4½ tons could be turned perfectly easily.

The president then returned the thanks of the meeting to the author of the paper, and the proceedings were adjourned.

(To be concluded in our next issue.)

RECENT PROGRESS IN DYNAMO-ELECTRIC MACHINES.*

By Professor SILVANUS P. THOMPSON, B.A., D.Sc., of University College, Bristol.

TWELVE months ago I had the honour of delivering in this place a course of three Cantor Lectures on "Dynamo-electric Machinery." In the first of those lectures, the author of dynamos, and to follow out a physical theory of the machine, the construction of such machines has been begun. In the second lecture, a large number of actual machines, chiefly of the Gramme type, were described and compared with one another and with the theory. In the third lecture, the dynamo was considered in its function as an electrical motor. As the present paper has no connection or supplementary to the Cantor Lectures, it will be convenient briefly to review the features of progress which seem to-night under the heads of the different order of topics. I, therefore, take up first the subject of Theory. There are, in fact, three distinct theories of the dynamo: (1) a physical theory, dealing with the lines of force and the lines of current in which these two sets of quantities are made, without further enquiry into their origin or law, the basis of all the work done by Dr. Hopkinson; (2) a theory, founded upon the mathematical laws of electric induction and of theoretical mechanics; and (3) a mathematical theory, based upon the possibility of representing the action of a dynamo by a so-called "characteristic" of the machine, a theory originally devised by Dr. Hopkinson, and subsequently developed by Fröhlich, Dupuy, and others. The last of these theories is the simplest. It has not received any great or striking development in the past year, but it is well to be reminded that during the past year, this proved itself to be the most convenient for practical purposes in constructional dynamo-machines. One use only to which this was made of characteristics by Mr. Kapp in his articles on the "Counter" of "compound" dynamos, and still more recently by Dr. Hopkinson, in solving certain problems in the electrical transmission of energy, to see how invariable the method is.

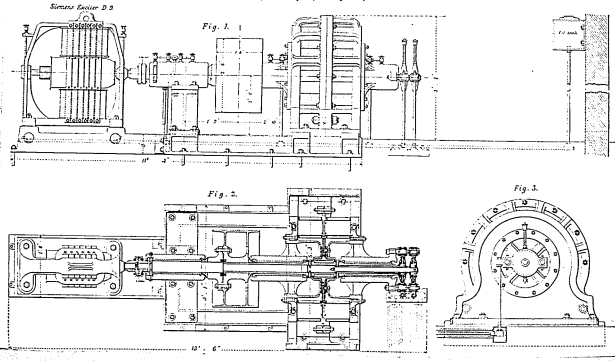
In the algebraic theory much progress has been made during the past year; and there certainly was room for it. Mr. Swinburne's has published, in the *Journal de Physique* for July 1883, a long mathematical article, the object of which is to deduce by mathematical methods the dynamo, taking into account not only the action of self-induction in the circuit, but also that of the turns of the wound coils upon one another, and upon the armature. It is a question whether he has not still omitted some terms of quite as great an importance as those he has retained in the complicated formula deduced by him. Another paper, equally by Lesser Clausius has published in Wiedemann's *Annalen*, for which the author has, I suppose, a mathematical theory of dynamo electric machines for sale. I mention it only that I may continue to say, for years here, that any other yet put forward. Without shirking any of the mathematical difficulties presented by the equations of mutual induction between, and self-induction in, the various organs of the machine, and by the absolute incompetence of all our formula for connecting the magnetism of a molecule with the strength of the magnetising current, Professor Clausius has succeeded in putting the equations into a shape, not only for more evidentially from the point of view of completeness, but in framing these equations in a manner that must commend itself to every engineer. The relative simplicity attained by Clausius is, in fact, due to his total exclusion of a set of arbitrary constants, each one of which having values that must be determined by experiment, for each machine or type of machine. The number of new symbols then introduced is considerable; and it would be very desirable to find names for the separate constants to be determined. An excellent translation of the paper in the *Philosophical Magazine* of this year, and another is in process of publication in the *Electrician*, in which journal the series of articles on the theory of dynamo-electric machines from the pen of Professor G. J. Lodge is still continued. It cannot be said even yet that the mathematical theory of the dynamo is near completion. A further study of the papers by Professor Clausius is required to see whether this article will deal with some of those which the graphic method of Mr. Kapp has left untouched, for example, in determining the proper quantities of wire for the shunt and series bobbins for "compound" machines, and in finding the best shape to give to magnets and armatures.

Turning to the physical theory of the dynamo, there is much to record. Our knowledge of the lines of force which go to form the field magnets and armatures of dynamos, has received considerable additions from Professor Ayrton and Perry, Professor Fleeming Jenkin, Professor Fitzgerald, and others. The re is a good deal of this knowledge which is not yet published, and I have several new results to announce as the result of my own observations. Let me first refer to the end-plate matter mentioned in my Cantor Lectures, namely, the distribution of potential round the end-plate of an armature. Mr. W. H. Preece, in a paper read before the Society of Telegraph Engineers, has given a very full and clear account of the distribution of potential round the end-plate of the Siemens armature, and has explained the method of observing it. Mr. Preece has also described the method of observing the lines of force in the interior of the armature, and the lines of the dynamo, and the other lines of force in the interior of the armature, and the lines of force in the interior

1000-LIGHT FERRANTI ELECTRIC GENERATOR.

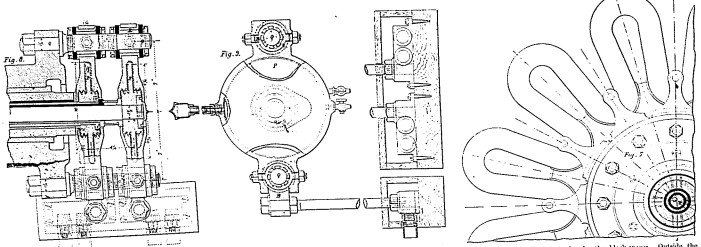
CONSTRUCTED BY THE HAMMOND ELECTRIC LIGHT COMPANY, LONDON.

(*For Description, see Page* 333.)



1000-LIGHT FERRANTI ELECTRIC GENERATOR.

CONSTRUCTED BY THE HAMMOND ELECTRIC LIGHT COMPANY, LONDON.



ELECTRIC LIGHTING AT THE INTERNATIONAL HEALTH EXHIBITION.

No. VIII.

Since the close of the Fisheries Exhibition, Messrs. Ferranti, Thompson and Ince have combined with the Hammond Electric Light Company, the business being carried on under the name of the latter firm. Consequently, although the Ferranti machines forms one of the most interesting exhibits at the Healthories, it is now to be found in the catalogue under the name of the Hammond Company, who in addition exhibits a 40-light Brush machine, and thus possesses both incandescent and arc lighting. The Brush lamps are not interesting in the grounds, but neither they nor the dynamos by which they are fed, call for an extended notice at our hands, for probably no system has received so much attention from the press and has undergone less modification since its introduction than this lighting is effected by a large

The incandescence capable of supplying 1000 lamps, Ferranti dynamo consists of that which we and similar in construction to that which we illustrate on the present page and on pages 332 and 336. The one shown in the engravings is part of an electric light plant recently erected by the Hammond Company at the works of Messrs. Colman and Co., of Norwich.

Fig. 1 is an elevation of the dynamo and the Siemens machine by which it is excited, mounted together on one baseplate. Fig. 2 is a sectional plan; Fig. 3 an end elevation of the Ferranti dynamo; Figs. 4 to 6 show enlarged sections of the armature, driving boss and the connections; Fig. 7 is an elevation of the same; and Figs. 8 and 9 are sections of the new mercury collectors, showing the modifications to the main leads. Since the engravings illustrating this dynamo considerable improvements have been made in its general construction. The main frame of this size of machine is made up of four parts. The sides have each 24 magnet cores cast upon them, and likewise carry, by means of arms or brackets (Figs. 1 and 3), an outer ring which serves to bolt the machine together and also to protect the armature. Round one-half of this ring a recess is turned and a corresponding projection is formed on the other, thus insuring that the two parts of the machine shall come true together. The bearing boxes are cast separately for convenience in casting, and also to allow of the bearings being got at easily.

The principal dimensions are shown on Figs. 1, 2, and 3. The weight of the cast-iron frame is 2 tons. When complete, without the pulley, the dynamo weighs 4 tons 10 cwt. The magnets are wound with double cotton covered wire 3.5 mm. in diameter, each coil being built on a separate mould and slipped on to its magnet core afterwards. The coils are forty-eight in number, and when coupled up in series have a resistance of 56 ohms. In practical use the two sides are coupled up parallel, and an exciting current of 30 amperes is used. The main bearings are 18½ in. long; they are of phosphor-bronze, close bushes being used. The spindle is Whitworth fluid compressed steel tube, hollow for lightness, and also to carry the main conductors to the outside collectors. Its diameter in the bearings is 4¼ in. The enlarged section (Fig. 4) shows the method of bushing and fixing the armature and the conductors. For convenience in the section in Fig. 4 does not follow a straight line through the armature, but is bent at the centre 90 deg. The reason of this is that each arm or division of the armature is different from the one at either side of it, and consequently if the section followed a straight line it would only illustrate one-half of the arrangements for the collection of the current.

According to Fig. 4, C is the hollow armature spindle, carrying within it two concentric copper tubes, to which all the copper strips on the armature are electrically connected. One end of the spindle is screwed to receive the driving boss D, which is fitted by two feather keys. The boss is made in two parts, like a face coupling, and the screws by which the halves are united bind it against a ring E on the shaft, and thus the boss is prevented from moving endwise. This boss has half as many arms as there are commutator bars on the armature, that is, six, and it secures every alternate one of these as shown in Fig. 5. The armature is entirely insulated from both sides of the boss and from the screws by vulcanised fibre, which is represented in the engraving by the black spaces. Outside the driving boss, but electrically separated from it, there is the outer boss G C, likewise made in two parts, and furnished with six arms which correspond to the six projections or depressions of the spoke to the six insulators provided for by the arms on the armature nut. These arms have rivets and ferrules, as shown in the lower part of Fig. 4, but unlike those on the driving boss they are connected, one by one, to one set of ends of the strips on the armature, and thus the boss G provides a path for the current on its way to the collector.

The other set of ends of the strips are connected at equal distances to a brass star or shaping piece H which forms a foundation for the armature. The arms of the star, as shown in Fig. 4, are laid off on a level with the rivets F F. The copper is laid from the star by the studs I I to the ring J, and through the star by the studs K K to the copper tube L L, on it and the studs K K to the copper tube L L, on it and the studs K K to the copper tube L L, on it and

ruined the speculation, and the works are now falling into decay.

The Gatineau Valley Railway is chartered to turn off from the Pacific Railway at Hull Station, 118 miles from Montreal, and to run up the Gatineau valley to the Desert Village, a thriving settlement at the mouth of the Desert River, and up this latter valley the road will some day be continued by James Bay, the southern prolongation of the Hudson's Bay, where in the neighbourhood probably of the old Moose Factory, the first and for years the principal trading post of the Hudson's Bay Company, will arise the new northern emporium of Canada, 465 miles north of Ottawa. There is an immense territory surrounding Moose Factory, Mesonna, comprising some 300,000 or 400,000 square miles, about which till lately but little was known, but which gives promise of being some day valuable. Moose Factory is in the latitude of London, and the temperature, though more varied, will average for the year round about the same as London. To the north of it on the eastern shore of the Hudson Bay are large deposits of coal and ironstone, whilst further south copper and other minerals are known to exist. The forest has been in a great measure burnt off by successive forest fires, and the ground that once was productive has been taken possession of, over large areas, by mosses and parasitical plants that impoverish the soil, making it wet and pasty; but that there are in this great isolated district some valuable resources, the testimony of all who have examined the country abundantly proves.

The Aylmer branch also comes in at Hull Station from the north-east, eight miles long to the foot of Lake Duchisne, an expansion of the Ottawa River. From this lake the rapids commence which, almost continuous for eight miles, terminate in the great Chaudière Falls of the river, at the city of Ottawa. This branch is now being extended by means of the Pontiac and Pacific Railway, some 70 or 80 miles through Pontiac county, to form an outlet for the produce principally of the forest and the farms of that district, which has not yet been nearly so fully occupied as from the good land it possesses and its proximity to the city of Ottawa it deserves to be. Hull, on the east bank of the Ottawa, opposite to the capital, is itself a city, and contains a population of over 8000 souls. It is on this side of the river that most of the large sawmills are built whose operations are on such a vast scale that some of them employ directly and indirectly 2000 men, and in some of the lumber yards there are often to be found prepared for market 20,000,000 ft. of sawn lumber in different sizes, ready to be shipped at a moment's notice.

Crossing the great bridge over the Ottawa, of which at the time of its erection, a full description was given (see ENGINEERING, vol. xxxi., page 357), the Pacific Railway comes to the end of its first section in the city of Ottawa, 120 miles from Montreal. It is scarcely a quarter of a century since the little village of Bytown, named after Colonel By, the engineer of the Rideau Canal, which here joins the Ottawa River and continues its navigation to the foot of Lake Ontario, emerged from insignificance, being selected by the Queen to be the capital of Canada, and became the city of Ottawa. It is now rapidly becoming an important railway centre in addition. The Pacific Company have practically four lines radiating from it to Montreal and Aylmer on the Quebec side of the river, the main line to the west, and their Brockville line on the Ontario side. Besides these they will shortly have a fifth important line when the Canadian Pacific Railway is open, which gives them a railway communication of their own to Toronto, Lake Huron, and the west, and they are now working as lessees the old Ottawa and Prescott Railway to the St. Lawrence and Ogdensburgh. Besides this the Canada Atlantic opens up a new district to Montreal and the north, the Gatineau valley and the Pontiac lines will open up two entirely new and at present isolated countries to the north, and at least two other chartered railways will probably shortly be completed on the Ontario side of the river to the south and west. The city of Ottawa itself is fast growing in wealth and population, the increasing work in the Government offices, the large lumbering establishments, and the concentrating railways are all adding to its population and importance, whilst factories and other permanent establishments are gradually increasing its wealth and influence.

The route forward is by the old Canada Central Railway, which became absorbed into the Pacific

[illegible] CORRESPONDENT

in the spring of 1881 (see ENGINEERING, vol. xxxi. pages 236, 196, and 245). In December, 1877, the two old roads, the Brockville and Ottawa and the Canada Central, which was then a line from Ottawa to Pembroke, amalgamated under the latter name, and in the spring of 1878 entered into a contract with the Government to extend their road to Callander, from which place the Pacific Railway was to commence, for which work they were to have a subvention of 12,000 dols. per mile for 128 miles, or 1,440,000 dols. altogether, Mr. Duncan M'Intyre taking a sub-contract from the company to execute the work. In 1879 Messrs. M'Intyre and Worthington, after considerable negotiation, completed the purchase of the old railway, and assumed the control. It was then on the 5 ft. 6 in. gauge, very much run down, and the rolling stock almost worn out. The new owners at once proceeded to put the line in order, equip it with new rolling stock on the standard gauge, and replace the old iron with new steel rails laid 44 lb. per yard. The works were at the same time pushed forward on the extension from Pembroke west, and by the end of June, 1880, the rails were laid to Chalk River, 21 miles, and the bridge over that river was being built. The old rails and rolling stock of the wide gauge were used for this work, and after the line was ballasted, new steel rails on the ordinary gauge were laid down and the line transferred to the company. By December, 1880, the line was finished to Mackay, 48 miles, while construction trains were running 10 miles further. On the 18th October, 1881, the railway was officially opened to Mattawa, 91 miles from Pembroke, the members of the Cabinet and a large party taking their places on the opening train.

The route from Ottawa as now worked runs for 29 miles over the Canada Central to Carleton Place, which is now, however, a very much more important depôt than in the old days of the struggling pioneer line. The Brockville line, which turns off here to the south, being connected not only with the Grand Trunk as before, but is now continued through the town and by a tunnel or ferry which takes the freight cars across the St. Lawrence without breaking bulk, with the Utica and Black River Railway in the State of New York. By this means a new and short route is opened direct to Lake Ontario and New York, Boston, and Philadelphia, and to Montreal by Prescott and forward by the Intercolonial Railway to Chalk River, the end of the second locomotive division, 126 miles from Ottawa and 246 miles from Montreal. Pembroke was till lately the terminus of the line, but the alteration to Chalk River was made as a more equitable division of the distance and a faster day's work for the men. The line west of Pembroke closely follows the south bank of the Ottawa River, and all the way to Mattawa is close to colonisation road which is made by the Ontario Government in connection with the free grants of land laid out through this section. Round Pembroke and half way to Chalk River the land is pretty good, but as the traveller goes west it gradually becomes rougher, and less and less valuable. The construction of the railway involved in places some very heavy work, and some long cutting west of Mackay, 600 ft. in length, was over 20 ft. in solid gneiss. To secure stability, trestling had to be largely resorted to, over which the trains could work to be completed, leaving the filling up to be contracted for and delayed the work in hand. West of Chalk River the road is pretty good, but at the Deux Rivières, 30 miles from Pembroke, the traveller goes west it gradually becomes rougher, and less and less valuable. The construction of the railway involved in places some very heavy work, and some long cutting west of Mackay, 600 ft. in length, was over 20 ft. in solid gneiss. To secure stability, trestling had to be largely resorted to, over which the trains could work to be completed, leaving the filling up to be contracted for and delayed the work in hand. West of Chalk River the road is pretty good, but at the Deux Rivières, 30 miles from Pembroke, the traveller goes over a considerable range of hills, and the road is very rough and hilly, and the rolling stock shows worn out. The new owners at once proceeded to put the line in order, equip it with new rolling stock on the standard gauge, and replace the old iron with new steel rails laid 44 lb. per yard. The works were at the same time pushed forward on the extension from Pembroke west, and by the end of June, 1880, the rails were laid to Chalk River, 21 miles, and the bridge over that river was being built. Mattawa is a pretty little village of yesterday. Here the great River Ottawa majestically sweeping down from the north, for it has here 500 miles from its source, is joined by the Mattawa from the west in a broad beautiful sheet of water from whence the combined stream continues its eastern course towards the ocean. On the point of land between the two rivers, the Hudson's Bay Company built a fort, which still remains surrounded by their reserve, whilst the village clustering round the railway station is on the south side of the Mattawa. It has already a population of 1000, and as this will always be the place where the lumbering supplies of the Upper Ottawa will leave the rail-

[illegible] CORRECT NUMBER OF DIVISIONS on [illegible]

way and take to the more primitive canoe, besides being the very paradise for tourists and sportsmen, this place will always have a steady permanent business of its own. There are already two sawmills erected here, and it is still a matter of doubt whether as railways are extended towards the great forest, sawmills will not work nearer to the source of their business, and send their sawn lumber by the railway rather than logs by the water. The lumbering on the Ottawa is an immense business; and it is estimated that the total cut of timber in this valley for the season of 1883 was not less than 800,000,000 ft., board measure, over 1,000,000 tons weight of boards. This is exclusive of the enormous quantity of railway ties or sleepers, telegraph poles, fencing, and other special timber that is procured to an enormous extent upon some of the tributaries of the great river.

After leaving Mattawa the country somewhat improves in appearance, and some very good farms are already dotting the landscape. Over this country the road was pushed rapidly, and by August of 1882 Callander was reached, or rather the point 120 miles from Pembroke, where Callendar was to be, and where the Pacific Railway proper was to begin, but as the whole system was now merged into one concern this is now only a roadside station of very unpretending importance. By the end of the year the rails were laid to the North Bay of Lake Nipissing, 19 miles west of Callender, 148 miles from Chalk River, and the end of the third locomotive division into which the whole road is cut up for the convenience of working.

TESTING DYNAMO MACHINES.

(Concluded from page 372).

Kempe and Fergusson's Electrical Resistance Counter.—The metal frame F F F (Fig. 5), into which is mounted the whole mechanism, is supported within a wooden casing. In the frame F F are fitted seven pinions *a*, *b*, *c*, *d*, *e*, *f*, *g* (Fig. 6), each of the pinions *b*, *c*, *d*, *e*, *f*, *g* is fitted a small cam *o*; and to the pinions *a*, *d*, *c*, *f*, *g* is fitted a multiplying wheel having ten times as many teeth as the pinions. These multiplying wheels do not gear into the pinions as in other counters of similar construction, but are free of each other. Upon the frames F F is fixed, free to move, a second frame A A, which carries five wheels *h*, *i*, *k*, *l*, *m*; these wheels are of the same size as the multiplying wheels, and are so arranged as to connect the first multiplying wheel and the seven pinions with each other. Whenever the instrument is in operation, the magnet M attracts and releases its armature, and the second lever L actuates the ratchet wheel R, and so sets the pinions *a* in motion; the counter will thus act on any ordinary electrical counter. We shall now describe the very ingenious mechanism by which the pinions *b*, *c*, *d*, *e*, *f*, *g* with their pointers, are placed at zero.

On turning the shaft H by the handle the cams C¹ and C² fixed to the shaft, are brought into action. The cam C¹ pushes the frame A A to the right, causing it to recede from the main set of pinions, whilst the two pins *p* and *p*¹ are fixed in the frame A A, and slide in the V-formed recess *x x* in the frame F F. Thus the main set of pinions and multiplying wheels are disengaged and become free. On further turning the handle the second cam C² becomes engaged in the bar B B. This bar has seven recesses in which, when at zero, the seven cams *o*, *o*, *o*, *o*, *o*, *o* can turn unhindered; but, whenever this bar is pushed by the cam C² to the left, the small cams *o*, *o* will be forced in the direction that their pins will allow, that is, by the cams thus pressed on the pinions and the pointers at zero, as shown in Fig. 7. On further turning the handle the cam C² disengages itself from the frame A A, and the bar B B is pulled back by the small springs S¹ S², and the five wheels engage again into the pinions and five multiplying wheels, which are still held by the bar B B. But as soon as the whole of the wheels engage in gear the cam C² releases the bar B B, which is then pulled back by the spiral spring S³, thus leaving the small cams *o*, *o*, *o*, *o*, *o*, *o* free, and the counter is ready for a new experiment.

This very interesting and original instrument has been of great service during the tests before us, and whenever a perfectly steady working engine is used during the experiment, no further and more reliable counter is required.

The engine employed by Mr. Heinrichs in these tests was an eight horse-power portable by Messrs. Marshall and Co., of Gainsborough. The speed could

London – Engineering – May 7 '85

THE EDISON SWAN EXHIBIT.

The Edison and Swan Company undertake the lighting of the entrance, the vestibule, and the South Court. In the former they place 400 Swan lamps of 16 candle-power, and in the two latter 200 lamps, partly of Swan and partly of Edison manufacture. The lamps will be placed alternately on separate circuits, one-half being driven by Edison-Hopkinson dynamos and the other by Edison "D" dynamos, the two batteries being on different engines, so as to avoid all the lights being extinguished at one time. The Edison-Hopkinson dynamos are the long 10-in. type designed to run at 800 revolutions and feed 450 lamps, requiring a current of 110 volts.

The original Edison dynamo has received great improvement at the hands of Dr. John Hopkinson, and while its general appearance has remained the same, its output has been very largely increased as the effect of new proportions in the magnets, pole-pieces, and coils. The result is that while the size of the machine has been decreased, and its weight reduced, the number of lamps that it will feed has been largely augmented and the efficiency has been raised. The latest type of machine is illustrated on page 445, where there is represented a dynamo designed to furnish a current of 250 ampères with an electro-motive force of 55 volts. The exterior dimensions are: Length, 56 in.; breadth, 36 in.; and height, 60 in., the net weight being 32 cwt. The resistance of the magnet coils is 7.54 ohms, and that of the armature .059 ohm. The commutator has forty divisions formed of copper bars insulated with mica, and the helix runs at 900 revolutions per minute. The efficiency of the machine is deduced from the following figures:

	Watts.	Horse-Power.
Total electrical power developed	16,246	21.78
Loss in magnets	691	0.54
,, armature	730	0.96
Power available in outer circuit when run with a current of 275 ampères and an electro-motive force of 55 volts ...	15,315	20.28
Hence		Per Cent.
Electrical efficiency	=	93.1
Loss in magnets	=	2.4
,, armature	=	4.5

A machine of this description will be shown in the Eastern Arcade, which has been run continuously for a fortnight without any stoppage whatever; at the end of this time the commutator was found to be quite smooth, and the brushes to have only worn $\frac{1}{16}$ in. There are two brushes on each holder, and they are independently adjustable.

There will be five L. Edison dynamos (page 445), each feeding 150 lamps. This type of machine needs very little explanation, as it has already been before the public for a long time. There are four columns on the field magnets, and a switch is mounted on the upper crossbar.

The general appearance of the Swan and Edison lamps is shown by the views on page 447, the former lamps being shown singly under a shade, and the latter in a five-armed group.

Messrs. Mather and Platt, of Salford, were from the first associated with the Manchester branch of the Edison Company, and built dynamos for them. Recently, however, they have brought out a dynamo machine of their own, and have devised several forms of driving gear designed to supersede the use of excessively high-speed engines. The engine and machine that this firm is showing at South Kensington is illustrated in Figs. 1, 2, 3, and 4, page 445, from which it will be seen that a pair of diagonal cylinders 8 in. in diameter by 10 in. stroke, drive on to a crankshaft fitted with a fly-wheel which is connected by a belt to the pulley on the dynamo. In order to give the strap more grip, it is carried round a tightening pulley riding loose on a stud fixed in a swivelling arm. The lower end of the arm is formed into a wheel quadrant gearing into a worm carried on a spindle at the end of the bed of the dynamo. By turning a handwheel on the spindle, the arm, and with it the pulley, is raised or lowered, and thus the strap is wrapped less or more round the pulley, as required, giving a neat and effective strap driving in a small space. The engine makes 175 revolutions per minute, and the gearing is in the proportion of 6 to 1. The dynamo is a modification of the Gramme machine, following the lines adopted by Dr. John Hopkinson in his reconstruction of the Edison generator. The magnet cores are of wrought iron, and are fitted with pole-pieces of enlarged section, the lower of which forms the bedplate of the machine. The commutator is formed of forty bars of toughened brass, and is of considerably larger section than is usual; it is provided with two brushes at each side, capable of separate adjustment, and arranged with elastic forks and thrust and butt contact. The machine is compound wound, and by reason of its efficient ventilation is capable of carrying a very heavy current, the one illustrated being designed to feed 200 lamps. The following is a list of Mather and Platt's dynamos:

No.	Number of 16-Candle Power Lamps to be fed.	Electromotive Force in Volts.	Current, in Ampères.	Speed.	Extreme Dimensions. Length.		Breadth.		Height.	
					ft.	in.	ft.	in.	ft.	in.
1	50 to 80	50	50	1650	2	7	2	1	2	6 × 4
2	81 — 120	50	75	1350	2	8	2	2	2	10 × 4
3	121 — 150	100	75	1650	3	1	2	6	3	0 × 4
4	150 — 200	100	100	1350	3	4	2	8	3	10 × 6
5	201 — 250	100	125	1050	4	0	3	0	4	1 × 6

A machine of this type, capable of feeding 250 lamps, is employed in lighting the stores occupied by the machinery of the Edison and Swan United Company, and for working lamps in connection with various ship fittings.

Cassell's Magazine

E. G.

Dynamos and Danger.

Dynamo-electric machines giving what are called "high tension currents"—that is to say, currents of high electro-motive force, say 1,000 to 3,000 volts—are known to have proved fatal to persons receiving the shock through their bodies by touching the two poles of the machine, or bare wires connected to them, at the same instant. It is not easy to suggest a remedy for this sense of things unless it be carefulness, combined with protection of the wires, or the disuse of such machines altogether, since they are not absolutely necessary to electric lighting. M. d'Arsonval, a French electrician, points out, however, that most of the accidents which have occurred were due to the "extra current" set up at the moment of making or breaking the dynamo circuit, and not to the normal current itself. He also proposes to correct this evil by absorbing these extra currents into secondary batteries, or voltameters, connected in series between the poles of the machine or across the two wires of the circuit. These voltameters are made of small lead plates immersed in dilute sulphuric acid, and as many are taken as will give a counter electro-motive force equal or greater than that of the dynamo. Having a high resistance they do not "shunt circuit," or shunt aside the current; but at the moment of closing or opening the circuit of the dynamo they absorb the extra spark, thus guarding the engineer of the dynamo against the evil effects of a shock from it.

ELECTRICAL DISCHARGES IN VACUO.*

By WARREN DE LA RUE, HUGO W. MÜLLER, and WILLIAM SPOTTISWOODE.

Some results obtained in working with a chloride of silver battery of 1080 cells, in connection with vacuum-tubes, appear to be of sufficient interest to induce us to communicate them to the Society, in anticipation of the more detailed account of an investigation which is now being prosecuted, and which it is intended to continue shortly with a battery of 5000 cells, and possibly with a far greater number.

The battery used up till now consists of 1080 cells, each being formed of a glass tube 6 inches (15·24 c.m.) long and 1 of an inch (2·0 c.m.) internal diameter: these are closed with a vulcanized rubber stopper (perb), perforated excentrically to permit the insertion of a zinc rod, carefully amalgamated, ⅛ to ⅜ (0·32 c.m.) of an inch in diameter, and 4·5 inches (11·43 c.m.) long. The other element consists of a flattened silver wire, passing by the side of the cork to the bottom of the tube, and covered—at the upper part above the chloride of silver, and until it passes the stopper—with thin sheet gutta-percha, for insulation, and to protect it from the action of the sulphur in the vulcanized corks: these wires are ⅛ of an inch (0·16 c.m.) broad and 8 inches (20·32 c.m.) long. In the bottom of the tube is placed 232·25 grains (14·59 grms.) chloride of silver in powder,—this constitutes the electrolyte; above the chloride of silver is poured a solution of common salt, containing 28 grms. chloride of sodium to 1 litre (1752 grains to 1 gallon) of water, to within about 1 inch (2·54 c.m.) of the cork. The connection between adjoining cells is made by passing a short piece of india-rubber tube over the zinc rod of one cell, and drawing the silver wire of the next cell through it so as to press against the zinc. The closing of the cells by means of a cork prevents the evaporation of water, and not only avoids this serious inconvenience, but also contributes to the effectiveness of the insulation. The tubes are

* A Paper read before the Royal Society.

height of fall 0·15". M. Spring thinks the formation of the drops has no influence on the velocity of flow; still, each of his experiments shows a diminution in the flow from the free orifice. M. Spring finds further that the influence of temperature adds itself to that of height of fall.

Coming now to the electrical phenomena, M. Spring demonstrates directly the production of electricity through formation of drops of mercury in the flow of the liquid from capillary tubes, and he proves that this production is not in the least due to friction of the mercury in the tube. This quantity of free electricity produced is of course very small, and only rendered sensible by apparatus of extreme delicacy, the idea of which was borrowed from M. Zollner. M. Spring was not able to assure himself experimentally that the mercury dropped is heated—although that an electric current traversing the mercury column from the exterior to the interior produces a very considerable increase and the inverse current a decrease in the quantity of mercury flowing out; and he was careful to eliminate all the secondary actions whose intervention was to be suspected. This influence exercised by electricity on the flow of mercury drop by drop leads him to conclude that the formation of the drops must be the cause of a production of electricity.

Lastly, he has observed that it is in dry atmosphere not having any electrical action on the mercury that the velocity of flow is greatest, and that there is a sensible retardation if the atmosphere is moist, or if it is of a nature to be capable of combining with mercury. According to him, the heating produced by neutralisation of the two electricities in the mercury drop, when these electricities have not to produce decomposition in the atmospheric medium, diminishes the capillary constant, and thus produces an increase in the velocity of flow; while, if the electricity of the drops is employed to separate the constituent elements of the surrounding atmosphere, this heating no longer exists, and there results a diminution in the velocity of flow. Perhaps to this the modifications in the state of aggregation of bodies which may be connected with the phenomena called catalytic. The above analysis will be sufficient to show the importance of the phenomena discovered by M. Spring in relation to the study of molecular actions.

LARY TUBES, AND THE ELECTRIC PHENOMENA ACCOMPANYING IT.

In a former communication to the Belgian Academy M. Spring enunciated, as a principle, that *every change in attractive energy is accompanied by a change in the electric state of bodies*—a principle of vast application, if generally verified. In a further memoir he investigates the electrical phenomena accompanying the flow of mercury in capillary tubes, with the view of verifying one of the consequences of this principle.

Considering the velocity of the flow, he studies the influence exercised on it by temperature, the capillary mesniscus, electricity, and the surrounding atmosphere. The influence of temperature is very sensible, with a height of fall of about 0·37". M. Spring has found that the weight of mercury flowing at the successive temperatures of 0°, 20°, 55°, 85°, were represented by the numbers 212, 228, 248, 261.

The influence of capillary mesniscus is also well marked; thus, with a height of fall of 0·39" M. Spring found that the weight of mercury which flowed with the orifice immersed was about 342 grammes, with free orifice 334. This influence is more considerable the less the fall, till the limit is reached at which the flow by drops ceases with a

Production of the Electric Effluve.—M. A. Bollet.

—The author, in experimenting upon the electrical action of the effluve, makes use of the following arrangement:—Two narrow tubes, filled with graphite in powder and calcined, and are parallel to and distant from each other. They are inserted with their whole length in a test-tube about 18 centimetres in length, and they terminate each with a platinum wire communicating with the exterior. The wire of one of these tubes traverses the test-tube to its upper part; the other is bent back in a downward direction. Two orifices enter the test-tube: the one exists at the summit, and the other penetrates to 2 or 3 centimetres of and the space to collect them. The effluve is produced in the space between the two carbon conductors.

Electric After-currents in Iron Rods.

It was discovered by Villari that if a rod of iron or steel through which a current has passed be agitated, an after-current is again set up in the same direction as the original current. He explained the phenomenon on the hypothesis that the rod is transversely magnetized by the current, and employing Ampere's theory of molecular currents, that these currents arrange themselves in concentric circles round the axis of the rod. Now, when the rod is agitated after the interruption of the current, the molecular magnets tend to mingle themselves irregularly again, and in doing so generate an induction current called by Villari an "agitation current." Prof. H. Streintz, at the Royal Academy of Sciences of Vienna, has recently, shown how to calculate the magnetic force exerted on the molecules exercuts by the original current in the rod. The problem is a case of Ampere's second theorem, that a rectilinear current of infinite length acts upon a pole of a magnet with a force inversely proportional to the perpendicular distance of the pole from the conductor. In the case in question we have to calculate the action of a circular surface (the rod being cut by) filled with uniform mass upon a mass-point situated in the surface. But a circular line with uniform mass exerts no action on a point situated in the enclosed surface, while it acts on an external point in the same plane as if the mass of the circle were collected in the centre. Therefore the force exerted upon a magnetic pole situated at the distance r from the axis $\rho = \frac{kr}{\pi}$, in which k is a constant, and π the semi-diameter of the rod. The total moment upon all the molecular magnets contained in the rod is then $\pi = \kappa / a$ where κ is a constant and l is the length of the rod.

Producing the Electric Glow.

M. Boillot has invented an apparatus which gives a very bright glow in gases with a comparatively feeble electric tension. It consists of a glass tube 50 centimetres long and several millimetres internal diameter, filled with powdered carbon, and hermetically closed; but having a platinum electrode sealed into each end. This line tube is enclosed in a second medium sized tube so as to leave a very narrow annular space between. These concentric tubes are then enclosed in a third wider one, and the space between the second and third tubes is also packed with powdered carbon. An electrode is also inserted into this carbon, and the ends of the latter are stiffened with shellac to prevent them falling out. The extremities of this larger tube are open. Different gases are then passed up the annular space between the inner and middle tubes, and when the terminals of the poles of an induction coil, fed by several cells, are connected to the carbons, a phosphorescent glow is seen to traverse the gas all along the tubes. By means of a medium sized induction coil and three or four Bunsen cells, M. Boillot has produced 20 milligrammes of ozone for every litre of oxygen gas submitted to the discharge.

Action of Light on Selenium.

Recent experiments of Mr. R. Sabine on this subject (see the *Phil. Mag.* for June) tend to prove that the impinging light effects a true decrease in the resistance of the selenium, rather than this of electro-motive force in the same direction as that of the battery.

ON THE INFLUENCE OF LIGHT UPON THE CONDUCTIVITY OF CRYSTALLINE SELENIUM.

By Werner Siemens.

The property of crystalline selenium first described by Willoughby Smith, and more closely studied by Sale,* viz. that in the illuminated condition it is a better conductor of electricity than in darkness, I have further investigated, and established the correctness of the facts. The specific conductivity however, of selenium made crystalline by heating to 100° or 150° C. is very slight and extraordinarily variable; the augmentation of the conductivity by illumination it also very inconstant; no dependence of the conductivity upon the illumination. But by protracted heating of amorphous selenium up to the temperature of 210° C., and *perature at 210° C.* (at which, with longer duration crystalline state), I succeeded in producing another modification of crystalline selenium, which possesses and permanently retains a considerably greater conductivity, and conducts electricity after the manner of metals, its conducting-power diminishing with rise of temperature. Also the action of the light upon it is far greater, and appears to be perfectly constant. By fusing into coarsely granular selenium two flat spirals of wire, at a distance of about 1 millim. from each other, between two thin plates of mica, I produced an extraordinarily sensitive photometer. With it obscure heat-rays are *without direct influence* upon the conductivity, which *is diminished by* heating the selenium; while diffused daylight doubles it, and direct sun-light in some circumstances raises it to *more than tenfold*. The augmentation of the conductivity of the coarsely granular selenium by illumination proceeds with extraordinary rapidity. Likewise the lessening of it on shutting off the light appears to commence instantaneously; yet a longer time elapses before the state corresponding to darkness is completely restored. The increment at the commencement of illumination is not proportional to the light-intensity, but a function of it which comes nearer to the ratio of the square root of that intensity.

I refer communicating details on this interesting property until the conclusion of my experiments, thereby fortifying that I hope to be able to utilize them for the construction of a reliable photometer. —*Monatsbericht der kön. preuss. Akademie der Wissenschaften zu Berlin*, 1875, p. 280.—*Philosophical Magazine.*

upon. No information was given to the meeting as to the ... likely to be pressed by the Government of the United States with regard to the concession obtained by the Direct Company under 41st. was, at least, a misapprehension. This is the more surprising, seeing that Mr. Pender might have justified his opinion by that of an American Senator, which has recently taken up the cudgels on behalf of the Company. We learn from that journal that "the authority for foreign conditions under which cables connecting foreign countries may be loaded on the shores of the United States, if it exists at all, resides solely in Congress, and until Congress sees fit to legislate on the subject, which it has not yet done, there is no power which can in any way interfere with the continental operation of the cable at Duxbury." But with all deference to our contemporary, this statement, at any rate, is in one sense decided error. We were inclined to think that if the matter was put it is represented to be in the columns of the *Journal of the Telegraph*, Mr. Pender would have long since secured the shareholders of the Direct Company that they had nothing to fear from the Assertion Government. His silence on this recent meeting, with such a piece of knowledge, has been severely startling. Besides, our contemporary evidently only guesses as to what Congress can do and what it cannot do, or the words, "if it exists at all," would surely have been left out of an otherwise positive declaration.

There might have been some little unpleasantness at the extraordinary meeting of the Mediterranean Extension Telegraph Company; but the shareholders present gave Sir James Carmichael the "cheer bill of health" he asked for, and the report and accounts were adopted. We notice it was asked why there was only one auditor to the company, and the reply was given that the company could not afford a second. Although the meeting otherwise appointed an honorary auditor, we are disposed to think that there might, under any circumstances, be two paid auditors. There is such a thing as being very wise and penny foolish.

We suppose the member of the board of the Eastern Extension Telegraph Company, who is shortly to be dispatched to Australia, is not the chairman. Important as the duplication of the company's cable may be, Mr. Pender probably feels that his presence in this country is of more importance at the moment. Otherwise, we should think the journey would suit him, and he would certainly return home with a greater popularity on telegraphy. The company is, we learn, soon to have purchased by the Australian Government, nor is it likely to buy, unless the Australian Government make a very tempting offer.

Since 1873 there have been a good deal of discussion respecting the failure of the negotiations between the Sheffield and the Great Northern and Midland Railway Companies; but the interest is now dying out. The agreement signed by the directors of the Sheffield Company was, of course, intended for a defeasor, but it utterly failed in its object. It is all very well for Sir Edward Watkin to assert that the Sheffield dividend will be 4½ per cent. for the current half-year. Probably it may. But to make that probability the ground of holding out for a perpetual dividend, when since 1849 the Company has never declared a dividend of 4 per cent., was manifestly absurd. The directors of the Great Northern and Midland Companies would have but the confidence of their shareholders at once had they consented to entertain the demand at all.

The directors of the Tower Circle Completion Company have, we believe, obtained the money they required, in spite of what we have stigmatized as unfair opposition on the part of the Metropolitan Board, and, subsequently, hostility from the City editor of the *Times*. In the statement which have from time to time been passed upon Mr. Crump we do not agree. We are persuaded that the influence of the *Times*' City articles is, on the whole, a potent for good than in days of yore, and we do not doubt that most of the persons who denounce Mr. Crump as an ignoramus or cuplines, have been wounded, in some way or other, by his righteous maledictions. But every now and then the public, and respecting the Inner Circle Completion Company we do fancy Mr. Crump made a mistake. It is true that the outset palpable that he did not look upon the scheme with favour, and although Mr. Parkes, in a temperate remonstrance, appeared to us to refute his criticism, he not only did not offer to make amends, but gave the Company another and more cruel stab. That the directors have succeeded in getting what they wanted, is not because investors are not guided by what the *Times* says, but because, for once, the City editor was manifestly wanted in argument.

"The Railway Autocracy; a question of vital importance to shareholders and directors alike overlooked," is the title of a somewhat stinging pamphlet from the pen of Mr. Edwin Phillips, the editor of the *Railway Service Gazette*. We cannot, however, agree with Mr. Phillips' main proposition which is, that a railway board can do anything, and we regret that Mr. Bass should have endorsed the theory, cleverly worked out though it be. We may, on another occasion, examine some of the arguments used in support of it.

SELENIUM.

By T. Fletcher, A.S.T.E.

The element selenium, owing to its great rarity and consequent costliness, has hitherto been but little known; and, but for the science of electricity, it would probably have remained so, more especially as neither it, nor any compound of it, has been employed in the arts. Of late years, however, a considerable amount of interest has attached to selenium in consequence of certain very remarkable characteristics which have been noticed in making experiments with it for electrical purposes. It is thought, therefore, that a slight sketch of these characteristics may not be out of place in these columns.

Selenium (*Σελήνη, the moon*), was discovered by Berzelius, and belongs to the class of elements which, like phosphorous, &c., appear to rank midway between the metals and the non-metals. It is obtained chiefly from Sweden, where it is found in certain pyrites used in the manufacture of sulphuric acid.

Selenium, like phosphorous, is susceptible of existing in three allotropic conditions (1), a red amorphous powder, fusing a little above 100° C.; (2), vitreous, brittle, deep brown, with metallic lustre, tasteless and odourless, a non-conductor of heat and electricity: this form becomes plastic above 100° C., and if heated to a little over 200° C. becomes crystalline and conducting: (3), crystalline rhumboidal prisms, which melt at 217° C. and boil at 700° C., and which can be obtained from the solution in bisulphide of carbon. It is only this latter form which is fit for electrical use. Its specific gravity is about 4·8.

During the laying of the 1865 Atlantic Cable, Mr. Willoughby Smith, who was in charge of the electrical department, devised a method of testing, since well known to electricians, by means of which com-

Death has been busy of late among our railway telegraph superintendents. Mr. Edward Cripps, of the London, Brighton, and South Coast Railway, died on May 15th, and Mr. Henry Mesan, of the Lancashire and Yorkshire, died on the 20th ult.

POLAR AURORAS.

By M. J. PLANTÉ.

"Nothing should be neglected which can bring about a complete conviction of the theory of the forces of nature, and cause the uncertainty of investigation to give place to the security of known truth. Should we, for example, be so sure of the theory of the rainbow as we are reproduced that brilliant phenomenon with all its peculiarities, by means of a jet of watery spray thrown up in full sunshine? The experiments of the laboratory are, though on a small scale, useful, and therefore to be valued."

These words, spoken by an illustrious member of the Academy, M. Babinet, encourage me to pursue the examination of the analogies between the effects of electric currents of high tension and the great natural electric manifestations. The experiment of De la Rive has already demonstrated the connection of polar auroras with terrestrial magnetism; but it does not sufficiently explain all the circumstances which accompany them. In the experiments described in the present paper, the electric stream flows in connection with aqueous masses as in the atmosphere, and a series of phenomena, completely analogous to the various phases of polar auroras, are observed.

1. If the positive electrode of the powerful secondary battery used in these experiments is brought into contact with the wet sides of a vessel containing a solution of salt and water, into which the negative electrode has been previously inserted, the following phenomena, varying as the distance from the liquid is increased or diminished, will be observed: either a crown formed of luminous particles making a circle around the electrode (fig. 1), or an arc bordered with a fringe of brilliant rays

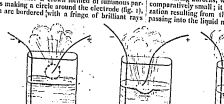

Fig. 1.

Fig. 2.

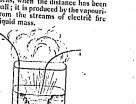

Fig. 3.

(fig. 2), or a wavy line which vibrates rapidly (fig. 3). This undulatory movement especially, offers a complete analogy with that which takes place in the aurora, been compared to the windings of a serpent, or to the motions of drapery shaken by the wind.

2. Although yellow light is predominant in these experiments, in consequence of the employment of salt and water, there have been observed, at these points where the water arising from the condensed vapour is less charged with salt, purple and violet tints similar to those of the aurora.

3. The rays of the luminous arc are produced by the flow of the electric stream into the liquid; the vacuum which results becomes again gradually filled up, new rays are formed, and an explanation is thus furnished of how the jets of light in the auroral *dark arc* appear to be thrown out and received every moment.

4. The circle or dark segment formed, in the auroras, by the mist or the nebulous veil which the electric stream meets with, corresponds to the humid circle or segment which, in the experiment, surrounds the electrode, and round which the vesicular current spreads itself.

5. The form of the arc in the voltameter is due to the fact that the liquid does not entirely surround the electrode; but, if the wire is more deeply immersed, waves and complete luminous circles are produced; just as in the auroras where the arc is often considered as the part, visible to the observer, of a complete luminous circle.

6. The liquid is violently agitated by the electric blast, eddies and luminous rings are formed by the shock of the electrified waves one against the other, and, if only a small quantity of liquid is used, a luminous cloud-like mist takes place, corresponding with that fluctuation of light which also characterizes the polar auroras.

7. The watery vapour is produced all the more quickly and in greater quantity, as the electrode sinks more deeply in the liquid. This phenomenon, which the strongest batteries of static electricity hardly give evidence of, is worthy of particular attention; for it explains, in a natural manner, the abundant falls of either rain or snow which have always been observed in connection with polar auroras.

8. The noise which accompanies these experiments corresponds with that which has often been heard during auroras, when the distance has been comparatively small; it is produced by the vaporization resulting from the streams of electric fire passing into the liquid mass.

9. The magnetic disturbances caused by auroras are reproduced in the experiments by placing a magnetized needle near the circuit. The deviation increases or diminishes as the luminous arc is more or less developed in the liquid.

10. The facts mentioned indicate that auroras must be produced by a flow of *positive* electricity; for the luminous phenomena are the same as those of the voltameter, and the negative electrode shows nothing like them.

11. But are polar auroras the result of a discharge between the positive electricity of the atmosphere and that of the earth assumed to be negative? If this were so, the fall of lightning gleams and luminous tufts be seen upon the prominent points of the surface of the ground, forming the counterpart of the phenomena which take place in the air. Observation, however, shows that such effects do not take place. I should be inclined therefore to think that it is the imperfect vacuum of the upper regions which, acting as an immense conducting envelope, plays the part of the negative electrode in the above described experiments; and that the positive electricity flows away towards the planetary spaces, and not towards the earth, through the fogs and frozen mists which float above the poles.

12. As for the origin of this polar electricity, it has been conceded that it comes from the equator and from the tropics. It may, however, be objected that the electrified clouds ought to discharge themselves in the course of so long a journey; and it is, in fact, known that storms become more and more rare as we approach the poles. By previous experiments, and others as yet unpublished, having led me to consider the celestial bodies as being charged with positive electricity (the only kind of electricity, perhaps, which exists), I should be inclined to regard the earth itself as charged with positive electricity, discharging itself, by means of simple emission, from both land and sea, which the strongest batteries of static electricity hardly give evidence of, is worthy of particular attention; for it explains, in a natural manner, the abundant falls of either rain or snow which have always been observed in connection with polar auroras.

8. The noise which accompanies these experiments corresponds with that which has often been heard during auroras, when the distance has been comparatively small; it is produced by the vaporization resulting from the streams of electric fire passing into the liquid mass.

9. The magnetic disturbances caused by auroras are reproduced in the experiments by placing a magnetized needle near the circuit. The deviation increases or diminishes as the luminous arc is more or less developed in the liquid.

10. The facts mentioned indicate that auroras must be produced by a flow of *positive* electricity; for the luminous phenomena are the same as those of the voltameter, and the negative electrode shows nothing like them.

11. But are polar auroras the result of a discharge between the positive electricity of the atmosphere and that of the earth assumed to be negative? If this were so, the fall of lightning ought to be frequently observed at the poles, or minent points of the surface of the ground, forming the counterpart of the phenomena which take place in the air. Observation, however, shows that such effects do not take place. I should be inclined therefore to think that it is the imperfect vacuum of the upper regions which, acting as an immense conducting envelope, plays the part of the negative electrode in the above described experiments; and that the positive electricity flows away towards the planetary spaces, and not towards the earth, through the fogs and frozen mists which float above the poles.

12. As for the origin of this polar electricity, it has been conceded that it comes from the equator and from the tropics. It may, however, be objected that the electrified clouds ought to discharge themselves in the course of so long a journey; and it is, in fact, known that storms become more and more rare as we approach the poles. By previous experiments, and others as yet unpublished, having led me to consider the celestial bodies as being charged with positive electricity (the only kind of electricity, perhaps, which exists), I should be inclined to regard the earth itself as charged with positive electricity, discharging itself, by means of simple emission, from both land and sea, radiating from the whole surface, at the poles as well as at the equator, the producing very different effects in consequence of the opposite meteorological conditions of the atmosphere in the two regions.

If this last hypothesis be admitted, it might be concluded that polar auroras result from the diffusion in the upper strata of the atmosphere around the magnetic pole, of the positive electricity arising from the polar regions themselves, either in obscure radiations when there is no interposed obstacle, or converted into heat and light through contact with watery masses either in a solid or liquid state, the latter being vaporized with noise, and precipitated afresh in the form of rain or snow upon the surface of the earth.—*Bulletin de l'Association Scientifique.*

[1] *On Stratified Discharge.—III. On a Rapid Contact-Breaker, and the Phenomena of the Arc.* By WILLIAM SPOTTISWOODE, M.A., F.R.S. Received January 20.

In a paper published in the Proceedings of the Royal Society, vol. xxiii. p. 455, I have described a new contact-breaker designed for as rapid as possible action of mains. It consisted of a steel rod which vibrated under the action of an electromagnet. As regards sharpness of break and steadiness as of definition in the arc, this instrument left little or nothing to be desired. But, as explained in the paper above quoted, an alteration in the current not only affected the steadiness directly but also reacted on the bar itself. The effects due to an alteration of the current alone thereby became masked, and the study of the laws relating to such changes was rendered more difficult, or altogether impracticable. In order to obviate this inconvenience I devised another form of contact-breaker, in which the vibrating rod and electromagnet were replaced by an arrangement purely mechanical in its action, and therefore entirely under control.

This instrument consists essentially of a wheel platinoid at the edge, on which a platinum spring rests. As the circumference of the wheel a number (40 in the first instance) of discs were cut, and these filed with the same edge so as to intermit the current. The breadth of the disc was about ¼ inch, and that of the teeth about ⅛ inch. The wheel was connected with suitable driving gear, so as to give from 250 to 2,000 revolutions per minute in each direction over a wheel. A 4-inch drift was found sufficient for the purpose, but after a few 48-ft drift by Appunto, as mentioned in recent communications, was preferable. With the wheel at rest the platinum springs bore, with a slight weight of several ounces upon the edge; but, on the other hand, high tension in the primary was necessary. In many of the experiments, two effective breaks to 20 of the so-called Leclanché cells were by mode employed with the wheel at rest, and from 20 to 40 with the wheel cut. But these were afterwards replaced by a double fluid battery suggested by my assistant, Mr. F. Ward, as I described at the end of this communication.

For some time the results were not pushed until with the platinum spring resting on the wheel; and the effects were varied by altering either the pressure of the spring or the velocity of the wheel; but the gradual abrasion of the platinum threw it friction proved to be a fruitful source of irregular results. This irregularity of action, at all times difficult to compensate, and sometimes inexplicable, was fortunately removed by a simple although important improvement. It was, in fact, found that metallic contact between the spring and wheel was not necessary, but that a thin layer of water would enable a current to be established. Such a layer was secured by a thin film of liquid drawn out between the rubbing from a reservoir and feeding on the wheel. Various fluids were tried, but the simplest and on the whole the best proved to be to dilute oil of vitriol, in the proportion of about 1 part acid to 6 drachms of water. Gas fully speaking, the better conductor the fluid is, the easier are the results obtained; but owing to the insulating skin being very narrow in this instance, a comparatively weak mixture of acid and water was necessary. In one wheel, where the insulating skin was 1/10 inch, the mixture 50 times as strong as in another, more wide. The spring, which under these circumstances became unnecessary, was replaced by a point, the adjustment of whose distance from the wheel was similar to that of a governor. This arrangement gave excellent results, even when the number of contacts which the wheel was capable of was raised to 250; but it is with the unpleasant and disturbing noise of the friction spring I am dealt.

Wheels having different numbers of teeth were also constructed; and although the results were unsatisfactory, being teeth of different breadths, as compared with the same velocity of rotation contacts of different durations. The low-ith of the double plugs, or length of interruption of the current, was unaltered, so long as the current was efficiently broken. It did not appear, however, that with the same tube more could be obtained with wheels having different numbers of teeth, than with the same wheels at different speeds. But it was found that for different tubes different wheels occasionally gave better results.

With the contact-breaker here described effects similar to those produced by the rapidly vibrating break were obtained. The arcs were formed in a regular manner, and presented or resolved, as resolved it was, no column usually, unbroken so long as the velocity of the wheel was maintained with sufficient rapidity. Under these circumstances, and with a proper intermediate velocity, arcs resolved into and beautiful bands, both ends at both sides, and sometimes appeared compact and continuous. Many of the phenomena always exhibited their characteristic features.

The condition of the arcs here described, whether flowing, or stationary, may be recognized under the general term "steady;" and when there is no motion in either

Electl News July 22, 75

direction, they may be specifically denominated as "rectifiers."

The facts have now been cited that no 1 or 2 can, what are the conditions necessary for the production of single strike? Secondly, what are the conditions and circumstances of the advance and retreat—in other words, of the four-of-steady series?

With a view of one standing the nature of the distinction between the ordinary and the steady strike, careful observations were made with the revolving mirror. It having been noticed that when the strike-in and steady ordinary or irregular strike were produced, and that when it ceased rapidly steady strike re-struck, it as most probable that the latter effect might be due to the short time of contact, and to the consequent absence of many of the factors described in Part II. of these researches. This is in fact identical with the suggestion there made, that the flattening appearance was due to the superposition of the up-strike and down-strike, not to the simultaneous arrival of the points at which they were respectively to be struck. The experiments of Part II., which, in fact, proved to be the case; for on the upper of the wheel was increased the distance at the disc being diminished; the image as seen in the mirror became narrower and simpler in its configuration, until when the set-up off of the produced each discharge showed only a single column of strike of a width proportional to the aperture with of the slit. The experiment so done, in-deed by the multiplicity of the individual strike in the c ntact, was still perceptible, and was directed as usual towards the negative pole.

From a comparison of the number of strike as seen by the eye with the one seen in the revolving mirror, it was found that the strike so formed were of the kind called "rain-bow" by the experimentalists. And the phenomenon of the flow of strike from the negative pole to the disc was found as before to be due to the series in succession discharge. If in each discharge the strike occupy no more in advance of those occurred in a previous discharge, the column will appear to advance; if the reverse be the case, there will appear to recede. If the positions remain unchanged, the column will appear stationary.

The following re-arrangement of the theories of the flow will easily occur to the reader, viz. that the rapidity of the flow will increase with the extent of advance made by the strike in each successive discharge, until that advance amounts to half the distance between two contiguous strike. Beyond this it is that the flow will have the appearance rapid to be followed by the unaided eye, and can only be observed by the aid of the mirror. When the strike of each discharge have exceeded the flow will go or be reversed. If the rate of advance will continue to increase, the rapidity of the apparent direction will appear in the same sense as the advance—hence to the exact distance between two contiguous strike, when it will appear to be stationary. Experiments appear to confirm this view of the case.

Experiments were next instituted with a view of ascertaining the connection between the flow and resistance. Starting from a condition of current and break for which the strike were stationary, it was found that an increase of resistance, introduced generally in the primary circuit, produced a forward flow, i.e. from the positive towards the negative terminal, while under similar circumstances a diminution of resistance produced a backward flow. Furthermore, a change producing a forward flow the resistance be continually increased, the flow, after increasing in rapidity so as to become indistinguishable by the unaided eye, gradually appears to become slower, and ultimately to assume its old, or occasionally with the few suggested above.

Another fact worthy of note also subsequently used. The principle upon which it was based was the

THE RADIOMETER AND ELECTRICITY.

The phenomena presented by this curious little instrument have awakened a lively interest on both sides of the channel, and though observations have been numerous, it can hardly be said that we have learned all from the radiometer that it is able to teach us. We recently referred to some interesting experiments by a Belgian observer, M. Dubaulx, who considered he had found in electricity the cause of the radiometer's motion, both direct and inverse. Prof. Stroumbo, of Athens (we learn from *Les Mondes*), has been experimenting in the same direction. Among other arrangements he constructed a radiometer having three platinum wires (which terminated in copper discs) soldered into the glass envelope of the instrument; two were on one side—viz., Disc A above the vanes and B below them; the other disc, C, on the other side, and below the vanes. A lighted candle being brought near, rotation occurred in the usual way from B to C. The candle was then put out, and when the radiometer had come to rest, a current of 3 or 4 elements was connected with a Ruhmkorff coil, and the extremities of the fine wire were connected, the positive pole with B and the negative with C. The radiometer then turned in the same direction as before. If, while it is turning under the influence of electricity, a lighted candle be brought near, the rotation is considerably increased. Thus the actions appear to be in the same direction.

While the radiometer was turning under the influence of a gas flame, the wires and discs B and C were connected with a galvanometer. The needle was deflected through an angle of 5°, and the effect would probably have been greater with a more delicate instrument. The radiometer had the same motion of rotation when the positive pole was connected with A, and the negative with C. On the other hand, if the poles be reversed, the positive being connected with C and the negative with B (or A), the radiometer at once not turn any more. If the positive pole was connected exteriorly with the top of the instrument, or its base, while the negative was connected with C, no motion occurred. Several other effects which M. Stroumbo obtained on applying his fingers to the glass support of a radiometer, whilst the envelope circularly-with silk cloth, pouring ether on it, &c., are connected by him with electrical influences.

In a recent paper to the Royal Society, Mr. Crookes called attention to some curious phenomena exhibited by a small piece of pith hanging down like a pendulum towards the rotating vanes of the radiometer, and about a millimetre distant from these. It was noticed that scarcely any movement of the pendulum occurred when the rotation was very rapid; but at one particular velocity the pendulum set up a considerable movement. At the suggestion of Prof. Stokes, the candle which produced the rotation was placed at the distance from the radiometer, for which a revolution of an rem of the fly synchronised with a vibration of the pendulum. In this way the pendulum was kept for some time swinging through a large arc.

Prof. Challis, in his study of the radiometer (*Philosophical Magazine*, November, 1876), has seen reasons to conclude that the light or heat in a radiant form, incident on the vanes, has the effect, after being transformed into heat of temperature, of so changing the relative positions of the atoms in a superficial stratum, as actually to incline the electric state. With this assumption, he proceeds to account for the phenomena described by Mr. Crookes. Since the radiant light or heat is converted into heat of temperature in a greater degree on the blackened surface of a vane than on the other, the two surfaces are electrified in different degrees, and relatively to a neutral state one is positively electrified, the other negatively. A face of the vane, whether positively or negatively electrified, will, on approaching the piece of pith, *attract it*; and the oppositely electrified face of the same vane, after passing the pith, will also attract it, supposing there is no contact between the vane and the pith. Thus the piece of pith is drawn in opposite directions in quick succession, if the rotation of the vanes be very rapid; and if impression of motion takes time, it might well happen that under these circumstances no perceptible motion takes place. If, however, the rotation is slow, the attraction of the vane in one direction may take effect before that in the opposite direction commences, in which case no oscillatory motion of the pithball will be produced. Clearly the oscillations will be most nearly when by reason of a synchronism of the time of oscillation of the pith with the time of revolution of the vane the attraction of a given vane acts like gravity on a pendulum. If the oscillations were due to action of the vanes on residual air, it seems hard to understand why there should be no perceptible effect when the rotation is very rapid.

No motion occurs in a radiometer before exhaustion of the globe, and the reason (according to Prof. Challis) is, that no electricity can pass, air of ordinary density being a non-conductor. On producing exhaustion, the rotation commences and increases up to a certain point, because rarefied air is a conductor of electricity. After a high degree of exhaustion is attained, the rate of rotation diminishes, because vacuum is a non-conductor of electricity. Such is the approach to that condition has a retarding effect. The vane continued to move after the degree of exhaustion was considerably greater than that at which the spark ceased to pass under the particular conditions arranged for the comparison.

On the Role in Electric Phenomena of Insulating Substances in contact with Conducting Bodies.—M. Neyreneuf.—In this paper the author first investigates the action of the insulating film in ordinary phenomena of condensation, as in the Blackburn experiment. He shows that this film does not absorb the charge, as is supposed, but that it acts, like the glass plate of the Ramsden machine, by influence on the conductors. He thus explains various experiments, (several of which are his own device), and definitely assimilates the condenser to the electrophorus. The electromotive force of the insulating plate, in a condenser, is opposite to that of the electrical source of the charge, just as the polarization of the electrodes in dynamic electrolysis occasions the production of a secondary current opposite in direction to that of the principal. M. Neyreneuf studies the circumstances, conditions, and limits of the charge and phenomena of discharge. He further studies the influence of electricity on gases, and describes a number of experiments with the terrestrial and with flames.

New Source of Electricity.—M. Donato Tomasi says:—When a current of steam is made to traverse, under a pressure of 2 to 6 atmospheres, a copper tube of 2 to 3 m.m. diameter wound spirally around an iron needle placed at some centimetres away from the magnetized during the whole period of the steam current through the tube. (Taken from *Comptes Rendus* of April 10, 1876.) In a subsequent communication of date M. Donato Tomasi quotes the following observations:—The important experiment of M. Donato Tomasi should, it seems to me, be interpreted by a very different consideration from that of the author. Heat does not act so as to produce "a new source of magnetism." It produces a thermo-electric current, generating the electro-magnetism, and is set up by the difference of temperature between the interior surfaces of the copper spiral traversed by the steam and the exterior surfaces exposed to the air. M. Tomasi ought to be able to reverse the current, and consequently the poles, by causing the heat to act so as to warm the exterior surfaces, at the same time maintaining the interior surfaces colder. (Taken from *Comptes Rendus* of May 3, 1875.)

Aurorae and Terrestrial Magnetism between Novaya Zemlia and Franz Joseph Land.—M. Weyprecht. —The author thinks there are maximum regions of Aurora in the north, and that this is one. The wonderful brilliancy of the phenomena greatly impressed him. With clear sky, aurora would be always be seen. These forms were distinguishable. Flaming auroras are generally followed by storms. The needle was never at rest in this region; some magnetic storms were taken, and among the chief results are these:—Magnetic disturbances are unusually strong there; they are closely connected with auroras, and greater the more quickly rapid the movement of the auroras and the more intense its prismatic rays. In all disturbances, the declination-needle was deflected eastwards, the horizontal intensity decreased, the inclination increased. M. Weyprecht hoped to have brought the auroras into connection with disturbances of galvanic earth currents; but, being 24 miles from land, he could only bury the collecting plates in ice, which is not a good conductor: so that only a small influence on the galvanometer needle was observed.—(From *Petermann's Mittheilungen*).

St. Elmo's Fire.—The rare phenomenon of St. Elmo's fire was observed at several localities in the Hare Mountains during the past month. At Blanksburg it occurred at a temperature of + 25° C. and pressure of 720.5 m.m., after a series of storms. The air was so laden with electricity, that cones held aloft emitted from their points light blue flames five inches in length and three in breadth. In Dibble the phenomenon occurred in the midst of a storm, half snow and half rain, when the ends of the branches in an entire grove were surmounted by flames from four to five inches in length.—*Nature*.

ROYAL INSTITUTION.

On the Action of Light on Selenium.

Dr. Siemens gave a lecture on this subject before the Members of the Royal Institution, on the 18th February last.

He commenced by reference to both the transient and permanent effects of light, to its action as a moving force and as a chemical motor, and closed his introduction by a statement of the hypothesis that it is not heat but the ray of light that breaks up carbonic acid in the leaves of plants, thus separating the carbon. Thereafter followed a description of selenium, considered from a chemical and physical point of view.

The first observation of the effect of light on crystalline selenium, viz., its increasing the conductivity, was made by Mr. May, a telegraph clerk at Valentia, and was communicated to the Society of Telegraph Engineers on the 12th February, 1873, by Mr. Willoughby Smith, a member of that body; this observation was confirmed by subsequent experiments. Within the last year, Professor Adams, of King's College, and Dr. Werner Siemens, of Berlin, have made independent inquiries: those of the latter formed the principal subject of the address.

The experiments on selenium were made through the resistance of a sensitive element, composed of two spirals of platinum wire, running parallel without touching, placed between two thin plates of mica, the interstices between the coils and mica being filled with molten selenium. The two ends of the coil protruded and served to insert the element in a galvanic circuit. The experiments showed that amorphous selenium did not conduct electricity either in light or darkness; that selenium formed by heating to 100° C. for some time and then cooling, showed an appreciable conductivity in light, but a very slight one in the dark. This selenium has been called modification No. 1, or electrolytic; modification No. 2 being metallic, is formed by heating to about 210° C. and keeping several hours at this temperature before cooling. Its conducting power is very much greater than that of the other modification.

The effect of temperature was also the subject of experiment.

An amorphous preparation of selenium is placed in a galvanic circuit and heated in an air bath, kept constantly at a temperature of 160° C.: it is found that up to 80° C. no current passes; that from this temperature to that of 150° C. the conductivity rapidly increases, whilst it again diminishes up to 230° C, at which point it reaches a minimum; on cooling, the conductivity varies in the same manner, but in a different ratio. On comparing the effects which are actually produced in heating the selenium, with what would take place if the selenium simply increased in temperature, it is found that there is a spontaneous liberation of heat between 90° C and 210° C, whilst there is an absorption during melting.

From a considerable number of these experimental results, Dr. Werner Siemens has extended Helmholz's theory that the conductivity of metals varies inversely as their temperature from the absolute zero, in substituting the expression total heat for temperature, and considers the specific heat of selenium to be an extremely variable quantity. His explanation of the action of light in selenium is, that there is a change of its molecular condition from the first, or electrolytic into the second, or metallic modification, or that, in other words, there is a liberation of specific heat upon the illuminated surface of the crystalline selenium, which liberated heat is reabsorbed when the liberating cause has ceased to act. This hypothesis is favoured by the circumstance that time is necessary for the complete dispersion of the effects of light, and that the effect of light is greatly diminished by long exposure, causing a readjustment of the specific heat through the mass, the galvanometer needle tending to return towards its zero position; this fatigue of the sensitive plate wears off by hours of rest, but days are required to restore the previous degree of sensitiveness.

The effect of the different rays of the spectrum upon the sensitive plate was also shown, the actinic and dark heat rays having no appreciable influence upon it.

Dr. Werner Siemens' selenium photometer was exhibited, which consists of a selenium plate not affected by the changes to which the substance is liable, mounted upon a vertical axis, upon which it can be turned through a certain angular distance limited by stops. By this instrument the intensity of light can be measured in a manner which is absolute for white light.

The lecture concluded with some experiments on a selenium eye, which Dr. C. William Siemens had constructed, to illustrate the sensitiveness of the selenium preparations. It consisted of a hollow ball with two openings opposite each other, the one being furnished with a lens of 4 inches in diameter, and protected with slides, representing eyelids, and the other having an adjustable stopper, carrying a sensitive plate, connected up to a galvanometer and one Daniell's element.

On placing an illuminated white screen before the eye, there was a very considerable deflection of the galvanometer needle, a red screen produced a smaller deflection, a blue a still smaller, and a black hardly any appreciable motion. The eye was also extremely sensitive to the different light rays of the spectrum, but was unaffected by the heat rays. As explained, it would not be difficult to make the eyelids close automatically under the influence of a very bright light, by arranging a contact and electro-magnet in connection with the galvanometer; thus imitating the automatic action produced by light on the natural eye.

An Electric Zoophyte.—A correspondent writes to a contemporary pointing out the fact that the ordinary *Zoophyton Flortiens* has a large natural store of electricity which it is capable of discharging into the water after the manner of the electric eel. Shocks have been felt from it by persons bathing. The writer charged a small Leyden jar with the discharge, the electricity being positive. After several experiments the Zoophyte became visibly weaker, and died in a few hours.

A pamphlet has been issued, entitled "The action of Light on Selenium," by Willoughby Smith. It contains a copy of a letter from Mr. Smith to the Secretary of the Society of Telegraph Engineers, dated March 3rd, 1876, giving a history of the discovery. It appears that in 1866, having to fit up the apparatus for his well-known system of testing submarine cables during the paying-out operations, which requires a resistance of 100 megohms, while searching for a better substance than gelatine to form the resistance, the high resistance of selenium was brought to his notice. "I obtained," writes Mr. Smith, "several specimens of selenium, and instructed Mr. May, my chief assistant at our works at Greenwich, to fit up the system we adopt on shore during the laying of cables, using selenium as the high resistance, and employing the spare members of the staff as though they were on shore duty, and to report to me on the subject. It was whilst these experiments were going on that it was noticed that the deflections varied according to the intensity of light falling on the selenium." The pamphlet also contains a letter to Mr. L. Clark, dated 18th February, 1873, giving details of the experiments. This was read before the Society of Telegraph Engineers.

Experiments on the Artificial Imitation of Magnetic Iron Ores.—Platinum.—Daubrée.—It is known that certain samples of native platinum not only act on the magnetised needle, but are even magnetic themselves, similar to true magnets. Berzelius, in a paper on the compositions of platinum minerals, noted this property in some nuggets from Nischne-Tagilsk (Ural), which he submitted to analysis. The antiferous sands of Oural, after repeated washings, leave a residuum in which the gold is mixed with a few platinum substances. To extract this substance a native magnetic oxide of iron and platinum is used, and after the action of a powerful magnet, the platinum ores that lie have a still further quantity of their particles. Such was the experiment undertaken by Daubrée, in 1866, from which he concluded that natural platinum nuggets are much stronger than natural crude iron magnets. Stanley analyses have shown that grains of platinum endowed with magnetism are always alloyed with a certain inconsiderable quantity of iron. Under or over a particular quantity the platinum becomes not magnetic, *i.e.*, capable of being attracted by the action of a magnet, is not itself magnetopolar. Now we know that magnetic mineral substances may, as a result of different operations, become magnetopolar; and Edmund Becquerel has shown that platinum, with traces of iron, under the action of energetic poles, may acquire likewise the magnetic property. The examples in which magnetopolar platinum nuggets (containing some traces of iron) were successful, is attributed by the author to the influence of the terrestrial globe. To ascertain whether such was the case, some platinum was melted with a small quantity of iron into the form of a bar, the mould, being carefully laid in the direction of the magnetic meridian. The melting was a small quite cold. Two very energetic magnetic poles found at its extremities, placed exactly like those of an ordinary magnetised needle; this was not a chance result. This goes to confirm the importance the globe's general action may have had in the distribution of the different poles of various magnetic minerals and rocks, at the moment when those minerals and rocks were first formed.

Tribution between Capillary and Electric Phenomena. —M. G. Lippmann.—The author sets out from an experiment by Kühne, which is thus:—A drop of mercury in pure or dilute sulphuric acid containing a little bichromate of potash. A polished iron wire is fixed in the neighbourhood, so as to dip in the acid and touch the mercury surface. Whenever it has touched, the drop is thrown into regular oscillations, which may continue for hours. The author explains this by the fact that the polarisation of the iron (according with hydrogen (electrolytically produces contraction in it, and the electrical heat has depolarising effect. He brings a number of experiments to prove that the capillary constant (function of surface, coefficient of Laplace's formula) at the contact surface of mercury and dilute sulphuric acid is a constant function of the electromotive force of polarisation at the same surface. On this principle he constructs a very sensitive capillary electrometer, also an electro-capillary motor. The latter is, briefly, as follows:—A tube filled with dilute sulphuric acid has two cylindrical vessels, containing some mercury, placed in it. Into the mercury, dip platinum wires connected with a Daniell battery, and also two wires from the sulphuric acid by glass tubes. Two jets of coarse glass tubes (open at both ends), with a long glass tube fixed in the mercury so inside, fixed with their lower halves in the mercury at the two cylinders, the sulphuric acid filling their upper halves. As the alternate up-and-down motion of these handles is kept in since ed, and this is effected by means of the pulsator and valves, shown, passing through the platinum wires, alternately polarises the one mercury mass with hydrogen, the other with oxygen. In his one case, the capillary constant, the capillary depression in and between the tubes, is increased, and the handle rises; in the other, the reverse occurs. This up-and-down motion is converted into circular by a simple arrangement of levers, &c.; a crank on the shaft works a key which reverses the currents. One of these oscillators went five days and nights with the same Daniell at a rate of 216 revolutions per minute; the speed falls off somewhat as the battery becomes exhausted. M. Lippmann further shows that the converse phenomenon, change of mechanical work into electrical, may be shown in the following manner:—Mercury and acid are in the standard position, and the wire must be formed. The galvanometer shows a current going through the dilute sulphuric acid from the outgoing electrode to the other, and the quantity of electricity is proportional to the masses of metals, but independent of its form. The author mentions some other interesting experiments in reference to polarisation by capillary forces.

Tel Journ Dec 15. 73

In a supplementary number of the *Philosophical Magazine* for December, Mr. R. Sabine describes some curious observations on electricity disengaged between mercury surfaces; and on the motions produced in mercury by oxidation. He concludes from his experiments (1), that the electricity disengaged between pure mercury surfaces (when not hydrogenised) is due to different states of oxidation; (2) that the motions observed to take place in mercury electrodes under water (or dilute sulphuric acid), are due to the displacement of the surface corresponding to the different atomic volumes of the metal and its suboxide (or subsalts and sulphate); (3) that the pumping action of a column of mercury in a tube or narrow channel is due to rapid circulations caused by such displacement; (4) that these motions are not due to change of either constant of capillarity or adhesion; and, finally, (5) that we may give a negative answer to Draper's question—viz., Is capillary attraction an electrical phenomenon? (In the same number will be found a paper by Mr. Lodge, "On a Mechanical Illustration of Thermo-Electric Phenomena.")

8/16

In an interesting communication to Nature, Mr. Robert Sabine states that the effect of surface tension upon mercury, on action of light or even slight solution, are strikingly shown when the mercurial forms one of the metals in a small voltaic cell. On constructing such a cell, by immersing a plate of amalgam covered with dilute sulphuric acid in a cell of water, in which a piece of platinum foil was likewise immersed, the current was first found to be electropositive to the platinum, but the difference of potentials between these metals soon fell to zero. On allowing a jet of air to impinge on the amalgam, a current was set up in the platinum in a direction opposite to that of the original current, and a steady deflection of 30° was obtained. This difference gradually lessened however as the spot was wiped so that the electrical equilibrium was restored, at which the difference of potentials, being equal and opposite in favour of the platinum, was then that which would have been were it the zinc. Mr Sabine found that the slightest shaking of the cell disturbed the electromotive force of the couple, and no sooner is motion the latter by means of a stirrer, the galvanometer needle immediately began as a steady deflection in the direction of daylight.

ELECTRIC RESISTANCE IN SELENIUM.—M. Fromme experimented with bars of selenium, 25 centimetres long and two millimetres in diameter, enclosed in a small tube with air expelling it in vain to allow a mass of fused sulphur to enter them. Such that the deflection of a galvanometer was due to light impulses is proportional to the number of elements in the last-mentioned, daylight produces the maximum effect, a ray only three millimetres but a small deflection. It should be stated, yellow gives the maximum and green the minimum effect. The rays of a lamp illuminated by yellow and red glass give a more powerful effect than when allowed to fall direct upon the mass. Certain solutions such as chloride of copper and nickel solutions intercept the active rays completely; whilst others, such as chloride of chromium, and above all the solution of selenium in very opaque sulphate of carbon, give a greater effect than direct radiation.

Telegraph Journ July 1, 75

ON PHENOMENA PRODUCED IN LIQUIDS BY ELECTRIC CURRENTS OF HIGH POTENTIAL.*

By M. GASTON PLANTÉ.

The author studied, with facility, the phenomena he now explains, by means of his secondary battery; whereas various observers (among whom were Davy, Grove, De la Rive, &c.), by using ordinary batteries, instead of a very high potential one, gave no satisfactory analysis to their investigations. If, for example, by allowing the passage of currents of variable intensity into liquids, we assist, so to speak, in the struggle between the electric flow and the two forces (molecular and chemical) which tend to maintain entire the metallic molecules of the electrodes, or the elements of the liquid decomposed at the voltameter. If the electric flow possess a high potential, the mechanical and calorific effects dominate, the molecular attraction is overcome first, the electrodes are disintegrated, fused, or volatilised. If the potential is somewhat less, the electrodes form the seat of luminous phenomena produced in the space and the resulted vapours surrounding them; the liquid, scarcely wetting the electrodes, is not decomposed without difficulty. Let the potential still further decrease, as also the principal calorific and luminous phenomena disappear, whilst chemical decomposition becomes manifested; and so, on the other hand, the current then traverses the liquid in a more complete manner, its strength will seem to be greater." Experiments were carried on with discharges from two secondary batteries—each composed of twenty lead plate couples—within a voltameter, containing a solution of diluted sulphuric acid. Various effects were produced, according to which pole was first plunged into the liquid, thus:

1. Plunge the positive platinum electrode into the voltameter. Let a piece of exposed platinum wire also form part of the external circuit, to show, by its appearance, the varying resistance of the circuit. If you plunge into the liquid the negative pole of the battery, covered in a shield of light vapour, without sensible disengagement of gas. The platinum wire in the air does not become red but in two or three minutes it becomes incandescent, the luminous sheath disappears, and an abundant release of gas takes place at both poles.

2. With a series of ten secondary batteries, whose discharge was equal to that from ten Bunsen's elements, in potential series, the same experiments was performed. On immersion of the negative pole, its fusion or volatilisation took place with a kind of explosion, and a flame diversely coloured, according to the metal employed. If the liquid contained but small traces of acid, so as to prevent the complete fusion of the metals, a continued series of sparks, accompanied with a crackling noise (analogous to that from induction instruments) was produced, and these sparks were lengthened for several minutes, by gradually decreasing the current's strength.

3. The most important phenomena arose from using a solution of chloride of sodium. On immersing the negative pole first, to a depth of 1 millimetre, and on bringing the positive pole into contact with the liquid, a small luminous globule, of perfect sphericity, was observed around the positive wire, with a noise. On lifting the wire, the globule increased to nearly 1 centimetre in diameter; by deeper immersion, a rapid gyratory movement ensued, and when it had acquired a certain speed, it detached itself, as though attached by the other electrode, its disappearance being accompanied with an explosion and a flame at the negative pole. The author, however, considers not to be gaseous, because the conditions of the experiment were not favourable to the decomposition of water. He considers it to be a liquid globule, in a particular spheroidal state, illuminated by the electricity it encloses.

4. Instead of plunging the wire into the middle of the liquid, let it approach the glass sides of the voltameter. A luminous eddy is produced, and a brilliant fumerous ensues, and when it has acquired a certain volume and detached the electrode, to a distance of 3 or 4 centimetres. Should it reach the neighbourhood of the negative electrode it occasions an explosion, or a noisy spark with flame, therefrom. The lesson sought to be taught from these phenomena is that these luminous globules, charged with electricity, animated by a revolving movement, producing a rippling furrow, and dispersing themselves with an explosion or noisy spark, present a reduced image of globular lightning, or thunderbolts.

Le Jour Oct 1, 75

DILATATION OF MAGNETISED CORES.—Messrs. Andrew and David Gray, of the Physical Laboratory, Glasgow University, have applied Edison's micro-tasimeter to the measurement of the lengthening and thickening of a bar of iron produced by magnetization and demagnetization. The magnetic effect was produced by the current from three of Thomson's Daniell cells, sent through a rough electro-magnet formed of four layers of six brass rods of bundled wire surrounded by a tube containing the iron wire to be magnetised. A deflection of fifty divisions on the sensitive scale of a reflecting galvanometer in the Wheatstone Bridge circuit indicated the elongation on magnetization. Further results of a quantitive kind are promised.

THE ELECTRICAL NEWS.

VOL. I. NO. 6.

ON THE CHANGES OF TEMPERATURE WHICH OCCUR IN PASSAGE OF AN ELECTRIC CURRENT FROM ONE METAL TO ANOTHER.

THE temperature-effect here denoted differs from that in passage of a current through a homogeneous conductor, inasmuch as it may be a cooling as well as a heating. The phenomenon was first observed by Peltier, in 1834.

Purgendorff showed that it must be closely connected with thermo-electricity, for heating took place at the junction point of the two metals, if the galvanic current flowed from the positive to the negative metal (according to the thermo-electric series), *e.g.*, from antimony to bismuth; and cooling, if it flowed in the opposite direction. It was discovered that in the circuit wire there was a thermo-electric excitation, the direction of which was opposite to that of the thermo-electric current.

The experiments of Quintus Icilius on this subject in 1853, and those of Fechner in 1854, shortly after, have been revised and criticised by Dr. Buff, in a recent instructive paper to *Poggendorff's Annalen*.

Quintus Icilius made a galvanic current of known strength pass, for thirty seconds, through a thin cylindric battery of antimony and bismuth bars. Then opposite changes of temperature were produced at the odd and the even solderings, and the effect of these was measured galvanometrically. From the observations it was inferred that the difference of temperature of the odd and even soldderings remained independent of the absolute heating of the metals, and was in direct proportion to the strength of the producing current.

There was, however, a slight but distinct increase of the quotient of thermal effect by strength of current, as the latter was increased. This curious fact was recognised, but did not explain.

Dr. Buff repeated this experiment thus:—Using a very sensitive metallic galvanometer, he did not require more than a single pair of cylindrical bars (4 mm. thick). These were plained and bound together with the fine surfaces opposed. To the outer ends of the bars copper wires were soldered, through which the principal current was passed (thirty seconds), then, by a quick transformer, the wires were connected with the metallic galvanometer. The thermo-electric couple was placed under a metallic vessel, to cut off the influence of air. A useful improvement was previously made of the indications of the metallic galvanometer with those of the current compass in the primary circuit. A deflection of 1° in the former being regarded as proportional to a deflecting force = 1, it appeared that up to 21° the deflecting force might be measured by the amount of the deflection. For greater deflections a necessary correction was made.

The first result was a gradual increase of the proportional thermal effect to the strength of the principal current; then it was observed that the temperature changes at the transition and even into metals in contact were approximately, but not exactly, proportional to the strength of the producing current. Dr. Buff discovered the reason of this. "The thermal effects," he says, "at the different points of junction of a thermo-electric battery, which take the form now of heating, now of cooling, and which we may denote by π, are always accompanied by heat actions, which are dependent on resistance to conduction, and, it is known, are proportional to the square of the strength of current. This second kind of actions, which we may call σ, are of constant influence on the galvanometer, when they are of equal strength at all the points of junction; on the other hand, when the places of contact are of unequal nature, they must become more and more perceptible with increasing strength of current, for their unequally active influences do not vary with the square of the strength of current, while that of π increases only in direct proportion to it. Now such inequalities are undoubtedly present in the thermo-electric pair described; for at the two ends copper wires were soldered, which, with the middle antimony and bismuth were only touching each other with plane surfaces, though of course pressed together. To remove any such disturbing influence, as much as possible, two bars were now soldered together with easily-fused metal, and the experiment repeated as above."

From the numbers given in a table it is shown, that through this intimate connection of the two bars, and the increase of points of contact at the bounding surface, the irregularities referred to as completely removed (at least within the limits of current strength selected). Hence the author considers it demonstrated that "the change of temperature in passage of the electric current from one metal to another exists in a law of proportionality to the strength of current more exactly, the more completely other causes of excitation of heat in the place of contact are excluded."

Fraulenhaim (as above stated) also studied this subject. After trying various modes of experiment, he finally decided to use Peltier's cross; which consists of two bars, bismuth and antimony (or the like), laid crosswise one on the other, and soldered together. Two neighbouring ends are connected with a galvanic battery and tangent compass, the two others with an astatic galvanometer.

Fraulenhaim considered that at the crossing point there were two heat effects: that due to ordinary resistance, and that dependent on passage from one metal to the other. If the former (σ) was independent of direction of the principal current; the latter (π) changed after the direction of current were reversed. Hence two equations $\pi + \sigma = a$, and $\pi - \sigma = b$, were found, which both π and σ could be deduced from proper experiments.

Dr. Buff considers that Fraulenhaim's experiments are invalid, because he sought to measure the temperature of the crossing point while the principal current was passing. (He had the other method failed to mistakes which did not allow of being calculated. The errors of these mistakes he did not explain).

Fraulenhaim, again, thought the current measured by his astatic galvanometer was the effect of thermo-electric action. But (Dr. Buff says) it is really in great part a branching of the principal current. To avoid this the experiment it will be found that the action on the double needle occurs with the greatest part of its strength immediately after closure of the principal circuit. If we suppose the strength of the first deflection, first observed, = α, the secondary circuit, and renew the experiment after the needle has come to rest, we generally observe only a slight change in the amount of the deflection from that first noted. A thermo-electric excitation must, however, unavoidably occur; but it can only be made distinctly perceptible after exclusion of the principal current, and by shortening the circuit of the thermo pile. Hence a more momentary action of the principal current must, in great part be produced, afterwards, a diminished deflection of the double needle; whereas, the galvanic circuit being kept closed for some time, there is a gradually increasing deflection of the double needle. (Dr. Buff mentions other facts as indicating that in the secondary circuit of the Peltier cross a branch of the principal current is present in considerable quantity).

If, now, in an antimony-bismuth cross, the principal current flows from antimony to bismuth, its branch x current flows in course through the antimony bar forwards; and the branch current y is taken by the thermo current depending on π and σ, since the place of contact is heated by both influences. Hence the action on the galvanometer is expressed by the equation $\alpha = x + y + \sigma$. If the principal current is sent in the direction bismuth to

Intent stimulation of the muscle and the electrotonus of the nerve.

The subject has since been studied by others, and recently, as we learn from *Naturforscher*, by M. Hermann Munk. Dr. Sanderson's observations were made on the leaves cut off;* M. Munk, on the other hand, has applied the unpolarizable electrodes to the uninjured leaves, and studied the distribution of tension. The phenomena which occur in this case we shall now shortly recount.

If the under surface of the leaf be first stabbed (that is, a current appears in part) *up* and direction, *i.e.*, flowing in the leaf from the end of the petiole or leaf-stalk (call it the *fore end* of the leaf), to the free end or point of the leaf (which may be called the *hinder end*). Points situated similarly on the two halves of the leaf are homogeneous, hence on the two sides of the midrib all is symmetrical.

Conceive the midrib divided into two unequal parts, a shorter hinder part and a longer fore part; then in each of these parts every point nearer the inner end is positive to every more distant point. The most positive point of the midrib lies about the fore end of its hindermost third, and with increasing distance from this point the positivity decreases towards both ends.

Suppose lines drawn on the surface of a half-leaf at right angles to the midrib; and call these, *cross lines* of the leaf. Every point of each a cross line proves negative to the corresponding point of the midrib; and regularly the negativity of these points increases first to a maximum, and then, on to the outer leaf-border, decreases. The most negative point of the cross line never coincides with the middle of the line, but is always nearer the leaf-border than the midrib.

By connecting the most negative points of all the sections, we have a principal line of length (*Hauptlängslinie*) nearly parallel to that of the midrib. All points in this line are homogeneous. So also are related points of other lines of length running parallel to the midrib, and lying inwards from the principal length-line. Of the middle parts of two cross lines, which are both in the fore or both in the hinder halves of the leaf-halves, the middle nearer to the fore or to the hinder leaf-border respectively, is always positive to the more distant middle, and the force, downward in the former case, upward in the latter, increases with the width of the leaf at this arch. The principal length-line, then, is the system of the most negative points of each leaf-half, while, in opposition, is of the hindermost third of the midrib. And, as side of the midrib so it each leaf-half all is symmetrical on the two sides of the midrib cross-to be disturbed only in that the most positive point in the midrib is displaced both from the middle.

The extirpation of the upper surface of the leaf offers great difficulties, owing to its sensitiveness. These having been overcome, it is found that the same distribution of tensions prevails as on the under surface. Indeed, between two similarly situated points on the two surfaces there is no difference of tension, so that it may be assumed that the absolute amount of tension on the two surfaces is the same. All these electromotive actions of the leaf of *Dionæa* are a lifeproperty of it, and gradually decrease as it gradually dies. They are further dependent on the state of nutrition of its leaf, and its fulness and vigour of life.

The absolute amount of the force is considerable. The difference of tension between a point in the region of the principal line of length, and a point in the hinder half of the midrib, is about one-tenth of a Daniell, and may even rise to one-fifth. Between other points of the leaf smaller values are had.

M. Munk proceeds to inquire as to the source of the electromotive actions. He concludes the forces must reside in the interior of the leaf, and cannot arise from heterogeneity of surfaces. By way of preliminary experiment, he had combinations of zinc-copper plates prepared, which, immersed in a conducting liquid, gave tensions on their surface similar to those found on the surface of the leaf. Thus a representation may be given of the electro-motive force probably operating within the leaf. The combination of two flat zinc cylinders, with copper-net interior, their bases turned toward each other, and the outer parts obliquely cut away, so that in the middle an obtuse angle is formed, and the whole immersed in a conducting liquid, represents approximately the electro-motive forces in question. In place of these two flat cylinders, conceive many small narrow cylinders of the same kind, placed much the same electro-motive force. Guided by these preliminary observations, M. Munk successively excludes, as possible seat of the electric forces, the disc-plasma, the sun-like hairs, the fibre-vascular canals, and the epidermis, so that there remains only the parenchyma; with regard to which he concludes that the roughly cylindrical cells of the parenchyma in the halves of the leaf, and that of the midrib, are endowed with forces of such a kind, that the positive electricity is driven from the middle of the cell to each of the two poles, which are positive to those in the middle.

The mechanical movements of the plant are of two kinds: stimulation movements, and resorption movements. In the former, the leaf closes very quickly after stimulation, within a minute or so, all parts moving simultaneously. In a few hours it begins to open again, and is quite open after 24–36 hours. It is then susceptible of further stimulation. The resorption movement, on the other hand, is more rare, and occurs when a small piece of flesh, albumen, or the like, is carefully laid on the leaf-surface, avoiding the sensitive hairs. The closure which follows is very slow, not beginning for some hours, and being completed only in 1–1½ days. The movements of the two halves are irregular and unsimultaneous, and depend on the piece of contact; from which they spread outwards. The re-opening begins after several days, and takes several days to be completed; and during this time the leaf is not, or is very little, susceptible of either stimulation or resorption movements. The leaf may die after one such resorption movement, and two or three always prove fatal to it; it opens no more.

M. Munk has occupied himself with the stimulation movement. It appears that the upper parts of the parenchyma of the leaf-halves and the upper midrib parenchyma, or at least its upper portion, are the stimulable parts: they may be stimulated by mechanical seizure, or removal of water in certain amount or with certain rapidity. M. Munk says the stimulation is propagated immediately over the whole parenchyma, and it relaxes. The relaxation occurs, as in *Mimosa*, through a flow of water from the interior of the stimulable parenchyma-cells, whereby the stiffness of the cells is diminished, and a good part of the escaping liquid goes into the parenchyma of the unstimulable parts. This is necessarily followed by movement, as the author explains.

We now come to the electrical phenomena in stimulation, of which Dr. Sanderson said that they presented a negative variation similar to that of the muscle-current. The electrodes were placed on the under surface of the midrib, as being the only part of the leaf which, during movement of the latter, does not alter in position. On stimulation through movement of the sensitive hair, there occurs, not a simple negative variation, but, as the author expresses it, a positive variation with negative after-many impulse (*Nachschlag*), which he calls double variation. This electrical phenomenon occurs even when, notwithstanding stimulation, there is no movement of the leaf. The latter circumstance renders possible an examination also of the leaf parenchyma; and the same double variation is here observed.

As to the explanation of this double variation, the supposition, that all the cells pass first through a negative then through a positive variation, is to be rejected as the process is rather this author thinks that through stimulation the cells of the upper halves of the half-leaf parenchyma and of the upper midrib parenchyma experience a negative variation, those of the under halves of the half-leaf parenchyma and of the under midrib parenchyma a positive, that is, the negativity of the middle of the cells to their poles increases in the former cells, on stimulation, and decreases in the latter.

As regards time-relations, the phenomena of variation and after-through, when the stimulation-movement begins.

ELECTRICAL APPARATUS FOR EXHIBITING THE ROTATION OF THE EARTH.—Mr. Geo. M. Hopkins, whose electrical gyroscope we illustrated in our number for August 15th, has applied the latter to demonstrate the earth's rotation. For this purpose the gyrating wheel with its electro-magnets is suspended by silk threads in the plane of the meridian, that is at right angles to the plane of the equator and parallel to the polar axis of the earth. The electrical contacts are made by metal discs carried by the wheel dipping into capacious mercury cups carried by the fixed support of the apparatus. A pointer attached to the wheel and a beam of light reflected from a mirror both serve to indicate on a scale the earth's angular velocity.

VARIATIONS OF CURRENT STRENGTH BY PRESSURE OR CONTACT.—As was found by De la Rive that when the circuit of a Daniell or Decretet electro-magnet is closed between the two poles no spark or sound is observed, but, on the contrary, when the circuit is opened a crack like a pistol-shot is heard. In 1834 it was shown by M. Trève that the same phenomenon, though in a less degree, took place in opening the circuit near a single pole of the electro-magnet, and, further, that the influence of that single pole equally determined the instantaneous stoppage of the little coils of copper originally united between the poles. In a recent communication to the French Academy of Sciences, M. Tobie points out that this experiment of De la Rive is an excellent means of showing that a large surface the influence of the pressure existing between two contacts on the intensity of the current traversing them. The ends of the wires of the electromagnet are held in the hands between its poles, and the noise attending the opening of the circuit can be varied considerably by leaving more or less strongly on one thread or the other. This noise, which is hardly perceptible when the two wires touch each other lightly, becomes like the report of a pistol when they are forcibly pressed together. Equally curious effects are to be noticed on making contact with pointed wires.

INFLUENCE OF ELECTRICITY ON VEGETATION.—M. Celi is conducting experiments on this interesting subject similar to those of M. Cornalia to which we recently alluded. This mode of operation consists in growing two similar seedlings in equal quantities of the same soil, water and air; the only difference between their conditions of growth being that one of them is grown in a specially electrified atmosphere. The apparatus consists of a water-dropping collector, that is, an insulated metal basin of water from which a fine jet is constantly flowing and breaking in spray. This basin consequently takes the potential of the surrounding atmosphere, positive ordinarily, but sometimes negative in broken weather. The plant to be electrified is enclosed in a bell jar, and a wire runs from the basin to a set of metal points within the bell jar which give off electricity to or take it from the jar. The non-electrified plant is also enclosed in a similar bell jar and in the same soil and water, but has no wire connecting it with any source of electrification. On July 12 last, three grains of maize of equal weight were sown under each of these bell jars. On August 1 they sprouted, and for two days kept pace with each other in their growth; but on the third day the electrified plants began to develope more rapidly than the others, and on August 10 the relative heights of the plants were 17 and 8 centimetres.

REMARKABLE ELECTRICAL PROPERTY OF GLYCERINE.—Professor Wullenhofen finds that when a cord is coated with glycerine on one side, and paint connected with conductors leading to the coatings of a Leyden jar, or the terminals of a Ruhmkorff coil, are placed in contact with opposite sides, but not exactly opposite each other, the positive is in contact with the coated side, the perforation by the discharge will invariably be opposite to the positive point instead of the negative, as in Zollin's experiment.

Relation between Electric and Capillary Phenomena.—By M. G. Lippmann.—(1). The surface of a drop of mercury placed in a glass vessel and surrounded with dilated sulphuric acid, quickly contracts, becoming more convex when placed in metallic communication with the zinc, but it re-expands when placed in contact with acid liquids. It may produce electric current which polarises the surface of the mercury. The experiment shows, first, that the contraction of the surface is due to a change in the capillary constant, this constant and the electromotive force of polarisation being continuous functions of one another; second, that, reciprocally, an extension of the surface produced by a purely mechanical action polarises it in the same manner as an electric current. (2) Variation of the capillary constant of a surface of mercury ascertained by hydrogen. The method employed consisted in polarising the top of a column of mercury contained in a glass tube by the current of a Daniell's element. The value of the capillary constant was taken by measuring the depression produced by the maximum. The same arrangement which furnished the capillary curves also measured the electromotive force of the polarised cell, and the initial deposition. The results have been confirmed and extended. The capillary constant varies from 361 to 423 millimetres, when the electromotive force of the polarisation varies from 0 to 1st Daniell. In employing a glass tube drawn to a slender point, of a diameter of about one m. m., altered under the objective of a microscope, we obtain a *capillary electrometer* of great sensibility, well adapted to measure electromotive forces. The free tension at the point of a Daniell element is measured by a pressure of more than one-third of an atmosphere. The approach of a freely-charged proof plane produces, by influence, a current which repels the mercury. (3). Polarisation produced by a variation of the surface.—By replacing the glass tube by a Thomson electrometer as modified by M. Kirchhoff, or by a quadrant electrometer, constructed by the author, of mercury, we find that the capillary constant of the surface and its electromotive force vary continuously whilst the surface is developing. The quantity of electricity produced may be measured in absolute units; it is independent of the form of the surface, and is simply proportional to the increase of area. These quantities change their sign when the surface diminishes instead of increases. (4.) Electrocapillary motors.—We are able to construct, by the principles given above, a motor which transforms indefinitely the current of the battery to mechanical work. Two masses of mercury, surrounded by sulphuric acid, may serve alternately for negative electrodes to the current of a Daniell's element. In each mass is partially immersed a bundle of glass tubes, open at both ends. At each inversion of the current one of the bundles ascends, the other descends. A system of levers transforms this alternate motion into rotary movement. The machine itself works by commutator. When we replace the battery by a galvanometer, and then work the system of the machine by hand, the needle is deflected during the rotation and in a direction which changes with that of the rotation.

Curious Electrical Experiment.—By M. Broche, of Toulouse.—I here a description of the following apparatus will be interesting. I do not know if it is new, but I have never seen it in any physical works. Two bands of paper are arranged as an armillary sphere, that is, the two circular bands of paper are placed at right angles. The bands at summit and base are pierced with two holes, in which passes a vertical axis terminated by two metallic cups or small plates of cork. This little apparatus is first upon an electrical machine, and the following are the phenomena observed:—If the finger be placed to the left or to the right of the apparatus, it turns from the right to the left or from left to right, according to the position of the finger. If the change in the position of the finger be made quickly, the change of movement is also instantaneous. If the finger be raised or lowered while the apparatus is revolving, it mounts or descends the length of wire. The pulse of the hand presented stops the movement. A metallic point produces the same result. During the rotation, a beautiful star appears at the end of the finger. A button of copper may replace the finger, but the movement is slower. M. Bahnsdorff has successfully repeated these experiments.

Researches on the Phenomena Produced in Liquids by Electric Currents of High Tension.—M. G. Planté.—The author employed secondary coils which use the largest inner (?) coil (?) giving 20 sign to the liquid of the voltameter. The two strongest results which seem to throw light on the origin of the fire-ball, or globular lightning, sometimes observed towards the end of an electric storm.

Animal Electricity.—An important paper on the electrical currents produced in animal electricity is published in the *Philosophical Transactions* for the present year. The author, Dr. Augustus D. Waller, finds that the phenomena of the electrical phenomena of muscle and nerve may be readily deduced from a few very simple propositions. Artificial muscle-column responds both to electrotonic and to excitative influences by an electric wave. The slight disturbance of the muscle-negative potential with respect to the unaltered. This, together with the doctrines of internal transverse currents in nerve and of the spatial-internal inverse nerve-excitation, appears fully competent to explain all the facts hitherto observed.

communication to the Royal Society.

Electric Fluorescence.—It has been found by M. Wiedemann that nearly all platino-cyanide double salts also fluorescence under the electric discharge; but so long as the are undecomposed no double fluorescence is observed. When platino-barium cyanide had been traversed by a single discharge, the strong fluorescent light showed no dichroism, but after a series of discharges it appeared. It also occurres when crystals of platino-various cyanide or other platino cyanide double salts were left a long time in vacuo (without electric discharge), whereby they lost water; and the more rapid appearance or dichroism under the electric discharge is attributed by him to the heating of the crystals.

Beethoven Feb 28 1880

the very opposite principle. Safety must be conveyed by a decided and unmistakable signal, the absence of which shall, in itself, be an indication of danger.

THE "ETHERIC" FORCE.

We often hear that "there is nothing new under the sun" and a fresh confirmation of the fact will be found in a paper on the "Phenomena of Induction," by Professor Edwin J. Houston, which appears in *The Journal of the Franklin Institute* for last month. The author it appears had, as far back as the commencement of the year 1871, published an account of some experiments made by him which, both in their method and results, bear a resemblance to those recently made by Mr. Edison; and they further seem to indicate that the action of the so-called "Etheric" force, of which so much has been heard of late, was observed then, and was settled as being nothing more nor less than the effects of Electrical Induction. Professor Houston says:—

The experiments alluded to were made with a Ruhmkorff induction coil, capable of throwing the sparks about six inches in free air. I found that by connecting one of the poles of the secondary coil with a gas pipe by means of a good conducting wire, and the other pole by similar means, either with a large insulated conductor or with a semi-insulated conductor, as for example, by allowing the wire to rest on a dry lecture table, that the volume or quantity of the spark was greatly increased, and at the same time the characteristic whitening of the condensed spark produced. These results I attributed entirely to a condensation of the spark by connection with extended surfaces, similar to the condensation produced by the introduction of a Leyden battery into the circuit.

During the progress of the experiments the following facts were noted, which bear upon the observations of Mr. Edison. While the interrupter of the coil was in operation, making and breaking contact with the battery, sparks could be drawn from any metallic objects in the neighbourhood of the coil, and, indeed, in adjoining rooms. For example, by holding a small metallic object in the hands, sparks were drawn, in an adjoining room, from a large pneumatic gas meter, from the well soldered joints with the water-pipes of the building. Similar sparks were drawn from a half-horse power engine, also in metallic connection with the water-pipes, and from the steam boiler in the chemical laboratory on the floor below. A person standing on the floor could draw sparks from any of the gas pipes in the adjoining rooms by holding a knife blade to the pipes or burners. These results I of course attributed to the action of the induced electricity from the coil, and published a note of them merely as a new experiment with the induction coil. On first hearing of the alleged discovery of the "Etheric Force" by Mr. Edison, I was led to think it probable that the phenomena observed by him were similar to those noticed by me in 1871, but from the brief descriptions published in the newspapers, was unwilling to make a public note of my belief. In the *N.Y. Tribune*, of December 9, however, Dr. Beard, of New York, has published a fuller account of the manner in which the experiments were conducted, and as far as I can gather they are of a similar nature to mine, and I feel warranted in believing that they can all find a satisfactory explanation by the presence of *induced electrical currents*, without the intervention of any new force whatever.

Immediately on reading the first published account of Mr. Edison's experiments, I repeated my original experiments in connection with my friend, Professor Elihu Thomson, of Philadelphia.

I append a brief description of our experiments. The induction coil already mentioned was worked by means of an electro-poin battery of ten cells coupled for an intensity of ten. The elements of each cell consist of a single plate of zinc placed between two plates of carbon. The available surface in each cell is about three by six inches. One pole of the battery was placed in metallic connection with a gas pipe and the other in similar connection with a large insulated conductor. On working the interrupting breakpiece, a torrent of characteristic white sparks of condensed electricity passed between the platinum points of the coil. Under these circumstances, that is, while the discharges were occurring between the points, sparks could be drawn from all metallic objects in the same room with the coil, or in adjoining rooms. The sparks were especially noticeable when metallic objects were approached to the gas or water pipes of the building, or to metallic surfaces in connection therewith, as in the case of the pneumatic trough, steam engines, and boiler before mentioned. As already implied, actual contact between the gas or water pipes and one of the wires leading from the coil, was unnecessary, as distinct sparks were afforded by a stove in the same room, and from another in an adjoining room.

In order to test the suspected similarity between these sparks and those described by Mr. Edison, we submitted them to the tests proposed by him. We made a number of experiments, and obtained the following general results, viz.:

First, The gold leaves of a delicate electroscope did not diverge on being brought into contact with the metallic objects yielding the sparks, although in every case the sparks could be seen at the point of contact.

Second. The needle of a delicate astatic galvanometer was not sensibly deflected by the sparks, on an apparent current being caused to traverse the coils of the instrument.

Third. A small shred of cotton wool was not sensibly attracted or repelled by pieces to which the spark might be obtained.

Fourth. The so-called retro-action of the spark was distinctly observed. On looping a wire back on itself, a decided spark was seen at the point of contact made by the end of the wire with any portion of the wire itself.

All the above results are in strict accordance with the known laws of electricity, as will appear hereafter.

To still further compare these results with those obtained by Mr. Edison, we dispensed with the use of the induction coil, and employed an apparatus similar to that described by him, viz.: An electro-magnet in connection with the battery already mentioned, the current of which was rendered intermittent by means of an ordinary

interrupter. With this arrangement, a wire in contact with the core of the magnet yielded sparks having all the properties described by Mr. Edison.

From a careful reading of the published accounts of Mr. Edison and Dr. Beard, it appears that the alleged discovery of a new force is based on their failure to obtain from the sparks, indications of electrical charges or currents; or in other words, in the apparent absence of electric polarity. All the effects noticed, however, are readily explainable by reference to the presence of an instantaneous outgoing current, immediately followed by an incoming one, with the complete re-establishment of electrical equilibrium. When we bear in mind the enormous velocity of electrical currents of this character, probably some hundred thousand miles per second, we can readily understand that the flow and reversion of the current would take place in an exceedingly small fraction of a second; a space of time insufficient, were the current merely direct, to produce any decided divergence of the leaves of the electroscope or the needle of the galvanometer. *The presence of the inverse current, immediately following the direct current, would absolutely and necessarily prevent the exhibition of electrical polarity as exhibited in the motion of the electroscope, galvanometer, and of similar instruments.*

It is doubtless due to the fact that the direct and inverse currents are opposite in their effects, and therefore produce instantaneous electrical equilibrium, that Mr. Edison failed to obtain the characteristic twitching of frogs' legs, or the discoloration of iodized paper; for, although these results would unquestionably follow an electric current in one direction, their presence would be masked by the opposite effects produced by the instantaneously following inverse current.

The possibility of the existence of the direct and inverse currents as above described, may be questioned; but when we bear in mind that the sparks can only be obtained by the interruption of the battery current, and that it is necessary to pass the battery current through a long coil of wire, conditions in every way favorable to the productions of instantaneous induced or extra currents; the direct and inverse currents follow as a matter of necessity; for the induced or extra currents in the coil of wire necessarily produce, in the core of the magnet and the metallic wire in connection therewith, an electrical current in one direction, instantaneously followed on the cessation of the induced or extra current; by a current in the opposite direction for the re-establishment of the electric equilibrium in the cores of the magnet.

It is a fact well known to all versed in electrical science that the induced current produced at the moment of making contact with the interrupter flows in the opposite direction to that produced on breaking the contact. This fact would in itself, exclusive of the above explanation, be sufficient to account for the production of inverse currents in the core of the magnet, when the interruption of the battery current was sufficiently rapid. Dr. Beard admits that the phenomena may be referred to a somewhat similar explanation, but the value from his subsequent adoption of the term "spalic force" as a preferable term to "etheric force."

It is matter of surprise to us that both Mr. Edison and Dr. Beard endeavored by careful insulation to eliminate in the apparatus employed by them the effects of induced electricity or science that the more perfect the insulation the more decided the effects of induction; of which perhaps, no better instance could be found than the care taken to thoroughly insulate the secondary coils in the induction or Ruhmkorff apparatus. In view of the above considerations, we feel warranted in the belief that all the phenomena noticed by Mr. Edison and Dr. Beard are explainable by the presence of inverse electrical currents of considerable quantity, but comparatively small intensity, instantaneously produced at the making or breaking of the battery circuit.

There was noticed during the progress of our experiments with the induction coil, the following curious phenomenon, which appears to us favorable to the explanations we have adduced. One of the poles of the coil was connected with a gas pipe and the other with an insulated conductor of considerable surface in the room containing the Ruhmkorff coil. This room is in connection by a telegraph wire with the chemical laboratory on the floor below, and with an earth circuit station, D, in another building, about five hundred feet distant in a direct line. On the interrupter of the coil being worked a peculiar clicking sound was heard by both of us in the line wire in the chemical laboratory. The operator at D was requested to observe whether any unusual phenomena were noticed at his instrument. He at once telegraphed to us that a distinct "tinkling sound" was heard, which did not vary whether the ordinary battery current of the line was opened or closed. Since he did not know what to expect, his confirmation of our observation was very satisfactory. The production of the sound is probably referable to a rapid succession of molecular changes produced in the wire by the sudden reversion of its electrical states.

Proceedings of Societies.

THE CHRISTMAS LECTURES AT THE ROYAL INSTITUTION.

By PROFESSOR TYNDALL.

(Continued from page 61.)

THE LEYDEN JAR AND THE ELECTRIC DISCHARGE.

Professor Tyndall's fifth lecture on Experimental Electricity, was devoted to the Leyden jar. He began by exhibiting the first form of this apparatus, as invented by Kleist, in 1745, and Cunæus, of Leyden, in 1746—1745. A phial three parts filled with water, with a nail fixed in the cork and plunged in the water. The nail was electrified, and the charge gave a smart shock when the phial was held in one hand and the nail touched with the other. The effect was increased by Wilson in 1746, who placed the phial containing water in a vessel so filled with water as to bring the surfaces of the liquid to the same level; and by Drs. Watson and Bevis, who substituted shot for the water inside the phial. Dr. Bevis coated a plate of glass with silver-foil on both sides, within about an inch of the edge; and Dr. Watson coated a phial inside and out with silver

no doubt, inventors and other students in telephony will take up the work and experimentally develope it further. So far, I feel satisfied in having discovered the principle and experimentally established the possibility of reproducing sounds by thermo-actions, through conversion of forces. A new route is thus opened to scientific research, and to progress in telephony.

THE ELECTRICAL PROPERTIES OF BEES WAX AND LEAD CHLORIDE.

By Professors J. PERRY and W. E. AYRTON.
Abstract of Paper read before Section A of the British Association, August, 1878.

PROFESSOR AYRTON commenced by noting the close way in which investigations in the various branches of physical science were linked one with another, and by remarking that experiments on electric absorption ought to have no less interest for the scientific engineer than those on the increasing strain of materials under constant mechanical stress had for the electrician. He then described how, in consequence of the absorbed charge in water being immeasurably greater than the surface charge, no direct method of determining experimentally the specific inductive capacity employed by Mr. Perry and himself, in their experiments on "Ice as an Electrolyte," failed to give the result equal to the square of the index of refraction for light of infinitely long waves, and he suggested that the method recently employed by Mr. Gordon for measuring the specific inductive capacity of rubble with very rapidly reversed charges might possibly, if applied to water, give an answer approximately more equal to the square of the index of refraction; however, he was inclined to think that, since Mr. Gordon's method for solids gave rather the application of the proper correcting factor for the thickness of the dielectric numbers closely agreeing with the received specific inductive capacities, there existed no known method for correctly ascertaining the electric capacity of a fluid.

For although a condenser might be made of opposed metallic plates separated by a space almost entirely filled with a liquid dielectric, which did not, however, touch either plate, and although, according to the arrangement would be solid to be insulated from the water, and the other, to be insulated from the paper on both sides—"Viscosity of Dielectrics," a succession of rapidly reversed charges would be accompanied by *true electric retardation* in fact that it would be worthy of consideration whether the experiments of the result which Mr. Gordon had brought to their notice at this meeting, viz., that his new method of measuring specific inductive capacity of solid dielectrics had given the old results might not be found to operate in this *conduction*—this viscous conduction he might term it, although in reality there was but one kind of conduction, the conversion of electric energy into heat—for this conduction would occur unequally in the two apparently balanced condensers, since the two dielectrics varied in viscosity, consequently the balance of capacities was not a real one.

Nevertheless Professor Ayrton thought it highly important that careful experiments should be made, both with constant and with rapidly reversed charges, on the inductive phenomena observed in such a water condenser as he had described.

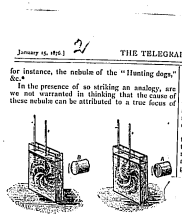
The abnormal rise in the specific inductive capacity of bees' wax, on solidifying, which the experiments of Professor Perry and himself had shown, coincided with an increase in the index of refraction; he regarded this as furnishing an important addition to the experimental proof of Professor Clerk-Maxwell's electro-magnetic theory of light, and he hoped that some of those philosophers of Trinity College, Dublin, who had so successfully turned their attention to the elucidation of the molecular vibrations causing Crookes' force, would give their views on the molecular vibrations accompanying wave motion and electric induction.

He thought that the experiments described in the paper on bees' wax and lead chloride showed, in a sufficiently satisfactory way, that, where the resistance of an electrolyte diminished by electrification, it was due to the electrometric force employed being sufficiently great to decompose the clamp in the pores of the electrolyte; but, in view of the fact that the resistance of water itself increased by electrification, it seemed to follow that the products of the decomposition of the clamp must act chemically on the solid electrolyte and cause deterioration, and hence a smaller specific resistance. But if there were deterioration we should expect that the specific resistance of the material would actually diminish day by day, a result that was not observed in the experiments of Professor Perry and himself, on bees' wax at any rate, as will be seen on examining the table given in the paper in the *Philosophical Magazine* for August. He therefore concluded that further experiments on electrolytes, in which resistance diminishes by electrification, were necessary to make the explanation quite complete.

ELECTRICITY IN FLOWERS.—Last evening a gentleman of this city accidentally made a most singular discovery, which has since been fully confirmed. He was passing through the store of Avery Sentell near the Music Hall, over which the vine was trained, and observed a flower attached to a single green thread upon the vine, which was fully extended straight out from the wall, and perceiving some of himself would do the same with which the stem was closed, there not placed there for the purpose of conducting the electric fluid of the atmosphere to the plant. In order to confirm this investigation he approached his finger within a half inch of it, and was startled to observe a slight electric impression—a just unmistakable motion of the stem. He then placed his finger a little nearer the stem; trembled violently and was seemingly attracted and repelled from him. The hairs which he noticed before did not do more, but remained erect. There was no wind at the time and the motion was purely an individual one. After this interesting experiment he touched the end of his finger within a short distance of the growing bud and slowly moved in a circular direction. The stem followed the motion until it was bent in the shape of a letter C, and when the finger was withdrawn instantly resumed the former straight position. This last experiment was witnessed by several persons, all of whom tried it with varying success.—*Lafayette (Ind.) Courier.*

for instance, the nebulæ of the "Hunting dogs," &c.*

In the presence of so striking an analogy, are we not warranted in thinking that the cause of these nebulæ can be attributed to a true focus of



electricity? whilst their special form may probably be owing to the presence of a strongly magnetic celestial body in the neighbourhood, and that the direction of the curvature of the rays may depend upon the nature of the magnetic pole turned towards the nebulæ.

We must then seek amidst the stars already known around these nebulæ for those which by their position may exercise magnetic influence, and explore the celestial vault upon the axis around which the spirals seem to turn in this or that direction, in a systematic manner, in order to discover the celestial bodies capable of influencing their forms or their gyratory movements. Further, if a star was found which satisfied these conditions, we should examine it upon the line passing through the centre of the nebulæ, and through the star itself, to see if there is not a point corresponding to the other pole of this star, and a second nebulous spiral having its rays turned in the reverse direction to the magnetic currents of the pole, but nevertheless appearing to the observer, turned in the same direction to those of the first; then the whole of these three bodies thus constitute a symmetrical stellar system. The cosmic matter is spread with such great profusion in space that this hypothesis is quite admissible.

Such researches require the employment of most powerful telescopes. I have suggested these theories to astronomers who have the reserve which should accompany inductions based upon simple analogy; but if observation justifies the assumption, it will afford a decided proof in favour of the electrical origin of spherical bodies. One might object that it would be impossible for a current of electricity to be conducted in space from the exterior to the centre of the nebulæ; in reply to this objection, I may remark that in other experiments with a source of electricity much more intense, I have observed little luminous rings formed by incandescent particles wholly detached from the electrode; these rings, the middle of which was agitated by a liquid vortex, move in the interval between the electrode and a larger luminous ring, formed by matter disturbed by the impulse of an electric wave against the partitions of the voltameter. These have the electrical fact separated from the principal ray to which they have given birth, and analogous, although infinitely small, to the origin of the isolated stars, or to those stellar agglomerations, for instance, which constitute the ring-shaped nebulæ of the "Harp," the "Swan," or the "Milky Way."

The last luminous ring which forms the limit of the development of the electric wave in the voltameter can even show the existence of immense nebulous rings hitherto invisible, which envelope all the others, and which is the last wave of the general electric movement of the universe.

ON NEBULOUS SPIRALS.

By M. F. PLANTÉ.

IF spectrum analysis has in later times allowed us to study the chemical constitution of celestial bodies, it is not rash at the present day to seek to give a reason for their physical constitution by the observation of electrical phenomena, and by the inferences that may be drawn from them.

The gyratory movements, accompanied by luminous effects, which I have observed with a powerful flow of electricity, the spherical and annular forms manifested by bodies under this influence, have already led me to surmise the probability of the electrical origin of celestial bodies.

I am able now to attribute the same origin to these worlds by a process of aggregation and disaggregation, which constitute the non-resolvable nebulæ, and particularly those which take the remarkable spiral forms.

I have some time since drawn attention to an experiment in which a cloud of metallic matter, attracted to an electrode by a current of electricity in the midst of a liquid, assumes a gyratory movement in the form of a spiral. It will suffice to look at Figs. 1 and 2, which represent this experiment, in order to recognise the exact form of the spiral nebulæ described by Lord Ross, the form of which have the curvature of their rays directed in the reverse direction to which the hands of a watch turn, like the rays in Fig. 1—such, for instance, as the nebulæ of the "Hair of Berenice," &c. Others have their rays directed in the same direction as the hands of a watch use, as those in Fig. 2, as

---

Selenium Experiments.

H. J. Moss has discovered that, when a bar of selenium is placed in the exhaust tube of a Sprengel pump and the air exhausted, the selenium becomes electrically conductive in the course of ninety hours. The selenium is then found to be covered with a delicate film of mercury, from the globules contained in the pump; and the conductivity is ascribed to this film.

* If we consider the moment when the metallic powder is in a state of rotation in the liquid, the resemblance to the rays of this latter nebula* in particular, is still more marked than in the figure referred to.

It is a well-known fact that muscles contract under the influence of electricity, and it is long since experiments were first made in the stimulation of dead bodies by this means. Some curious phenomena have been obtained in this way. Recently, Dr. Keppeler, of the hospital of Mannheimgen, has added some new observations on the subject. He subjected twenty corpses to the action of various electric currents, and noted the rate of disappearance of the electri g-muscular contractility. In persons emaciated by long chronic maladies, this disappeared much more rapidly than in robust individuals, or those who had had acute maladies. It disappeared five quarters of an hour after death, at the quickest, and six-and-a-half hours at the slowest. It is in cases where a rise of temperature is observed after death (which are not extremely rare), that the electric contractility persists longest. The importance of this sign of death is evident if we reflect that the contractions under electricity continue intact so long as there remains the least life. In the most prolonged faints, in the deepest lethargies, in all the varieties of apparent death, poisonings by carbonic oxide, chloroform, or narcotic substances, this valuable sign can be had at will, so long as real death is not a *fait accomplit*. The fact of death, too, can be thus ascertained without the necessity of awaiting other certain signs of death. Some interesting cases in this connection are related by Dr. Keppeler in his paper, which appears in the *Bibliothèque Universelle* for November.

between this interval and the extent of the barometric variation, judging by the frequency with which the thermometric change followed at a short interval after an extensive change in the barometer, the consequent variation in pressure affecting the more or less rapid development of heat. Frequently when the extension of the magnet was extensive, the change in the barometer and thermometer are less active, exhibiting a tremulous or perturbed result. Sometimes the contrary only behaves in this way. The variations of the thermometer descends in winter, but it still retains the variations in rapport with those of the results of the barometer.

The following table would also show that a relation exists between the direction of the magnetic variation and the rise or fall in the barometer and thermometer. The years 1848 and 1851 are selected at random, and the maxima and minima are those of the maximum wave-line on each date.

Mr. Broun. Observ.'s Assist.'s	Chiswick: September.						
	Magnetic Variation Sept. 1851	Barometer 1848.		Thermometer 1848.	Barometer 1851.	Thermometer 1851.	
E.	W.	Max	Min	Max	Min.	Max	Min.
—	8 2	—	—	4	—	3	—
4	4	8	3	13	7	4	4
7	7	9	3	13	7	7	7
11	11	10	10	17	11	11	11
13	12	16	10	17	13	13	13
16	17	15	11	20	19	20	16-19
—	—	21	21	22	21	20	21
—	21-23	Gradual rise from 21 to 23		23	—	22	22
24	27	27	—	23	24	18	24
28-30	—	—	26	16	29-30	13	—

This table shows that an E. magnetic variation is attended by a maximum barometer and thermometer, and the W. variation by these at a minimum.

The following extract is from a paper by Mr. T. Hopkins on the Meteorology of January:—"At about 10 a.m. the barometer ceases to rise, and shortly afterwards begins to fall, and it continues falling until 4 p.m., although the cooling of the wet-bulb thermometer has by that time ceased. From 10 until 1 or 2 o'clock, the time of the highest temperature, vapour must be rapidly mixed into the atmosphere in increasing quantities; and the vapour must be presumed to accumulate in the atmosphere until 4 o'clock, as the evaporation generally continues active up to that hour, and no decline of the dew-point indicates the condensation of any portion of the vapour thus produced. Now, if increase of vapour had raised the barometer up to 10 o'clock, why should not a further accumulation of vapour after that hour raise the barometer still higher? The fall of the barometer after 10 o'clock, in fine weather, must be accounted for from the operation of the causes named."

The force of this is evident in connection with the theories advanced in these papers. The part of the surface of the earth turning towards the sun, and receiving from the great source of atmospheric agitation, the pressure from without our system. The consequent increasing evaporation together until about 10 o'clock, when the force *ab extra* diminishes, and the balance of vapour alone cannot maintain the increased column at its previous altitude. When, by the rotation of the earth on its axis, that part of the earth's surface under observation approaches the force *ab extra* about 4 o'clock, the effect of its power is observed in the increased altitude of the mercury. No previous theory could explain this, and the same as regards the following:—

Mr. Broun found that the semi-diurnal variation of the barometer was greater in winter than in summer.§ He also notes in the same memoir that the barometric variation during the day in

NOTES ON SOME ELECTRICAL PHENOMENA.

No. VIII.

(Continued from Vol. XIX., p. 476.)

WHILST computing a mass of meteorological observations in reference to electro-magnetic theories advanced in three papers, the writer has met with some results that may, perhaps, interest those of our readers who study these theories.

The rapport between the magnetic and barometric variation was has already been detailed and illustrated by Mr. Broun. The pressure developed by the electric disturbances in the stars, more particularly from their enormous ovenidences, is disclosed by the varying height of the barometer, and, on occasions, especially when sudden, generates heat, it might reasonably be supposed that a variation in the thermometer would also occur in rapport with the magnetic and barometric variations. As far as the writer's investigations have extended he finds such to be actually the case, that there is a decided relation between the thermometric and the barometric fluctuations, the former following the latter generally after an interval of from two to four days, which lapse of time is the action on our system *ab extra* is like that of our star whilst it, seeing that the greatest heat of the day does not occur at noon, but some time after. There also appears to be a relation

Journal de Physique, III., No. 34, Oct. 1874.—This number commences with the first portion of a paper by M. J. Bertrand, entitled "Demonstration of Thomson's rule relative to Electro-dynamic Actions." The object of this paper is to simplify Ampère's demonstration of the theorem of electrodynamics.—Arrangement for obtaining projections of the metallic rays and amphyglogen fluxe, the latter employs a mixture of the chloride of the metal with one-sixth of its weight of powdered gum-lac, provided with a vertical slit. Reversals of the metallic lines are effected by allowing a beam of white light (transmitted or sun-light) to pass through the disfigurating mixture and, analyzing the resulting ray by prisms. By allowing the sun-light to fall only on one-half of the slit, the coincidence of bright with dark lines can be shown.—M. Mercet contributes a paper describing two pieces of apparatus for obtaining the placement of isoclinic lines.—On the magnetisation of steel, by M. E. Bourg.—This number contains a translation of Lord Rayleigh's paper on the manometer and theory of diffraction gratings from the *Philosophical Magazine* for February and March.—Sensibility of silver iodide to rays supposed to be chemically inactive, by H. Vogel, from *Pogg. Ann. of Chemistry*.—From the same journal there is a paper by H. Seeliger, on changes in the length and elasticity of a wire under the influence of an electric current.—From the Proc. Roy. Soc. there are translations of Prof. Tyndall's paper on the transmission of sound, and Mr. Norman Lockyer's note on a new law of absorption phenomena.

EARTH CURRENTS.—Cappanera notices that earth currents are strongest in certain volcanic districts. At Potenza they are strongest in the neighbourhood of the Monte Vulture (mount of Vultures, and are most noticeable in October, November, December, March, and April, especially during heavy falls of snow.

Mr. Preece's Speaking Telegraph.

We have had a sealed account of an invention of speaking by telegraphy have been shown to us, but we are still quite in ignorance of the nature of this invention, it would be well to have the complete secret before we occupy ourselves much on the matter for some time to scientific men. The following plan has been described to us, and our friends, and, no doubt, has suggested itself to many acquainted with the physical discoveries of the last four years. It is simply carried out between the elaborate nature, and on account of its expensive character, we should we recommend its being carried out in this form. But if the new American invention, to which reference has been made, should turn out to be some plan of this kind, then this letter may be good in preventing monopoly in an invention which really is the joint property of Willoughby Smith, Siemens, and other scientific men, rather than of a particular man who has had sufficient money and leisure to carry out the idea. The plan, which was suggested to us some three years ago more immediately by a picture in *Punch*, and governed by Willoughby Smith's experiments, is simply—Let the transmitter at a station of a large surface made up of very small square squares of selenium. One end of every piece was connected by an insulated wire with the distant place, i, and the other end of each piece connected by a wire to the earth. With the plan commonly employed with telegraph instruments. The object whose image was to be sent by telegraph was illuminated very strongly, and, by means of a lens, a very large image thrown on the surface of the transmitter. Now it is well known that if each little piece of selenium forms part of a circuit in which there is a constant electromotive force, say of a Voltaic battery, the current passing through each piece will depend on the illumination. Hence the whole Voltaic current in each telegraph wire would depend on the illumination of its extremity. Suppose, then, that each piece, 1, was, in our original plan, a collection of opposite cells, the position of each of which (as in the ordinary needle telegraph) was controlled by the electric current passing through the particular telegraph wire with which it was connected. Each magnet, by its movement, closed or opened an aperture through which light reached to illuminate the back of a small square of frosted glass. There were, of course, as many of these illuminated squares at 2 as of selenium squares at A, and it is quite evident that since the illumination of each square depends on the strength of the current in its circuit, and this current depends on the illumination of the selenium at the other end of the wire, the image of a distant object would in this way be transmitted as a mosaic by electricity.

A more promising arrangement, suggested by Prof. Kerr's experiments, consisted in having each little square at a route of silvered soft iron, and forming the end of the core round which

NOTE.—All degrees of temperature are Centigrade, unless otherwise mentioned.

Comptes Rendus Hebdomadaires des Seances, de l'Academie des Sciences. No. 1, January 12, 1875.

Memoir on Electro-Capillary Actions, Treating of (a) the Depolarization of the Electrodes, as well as of the Electric Effects Produced at the Point of Contact of the Membrane and of Various Liquids; (2) the Relations between the Electromotive Forces, the Quantities of Heat Liberated during their Production, and the Diffusive Powers.—M. Becquerel.—The names of this paper appears sufficiently from the title. The author considers that he has arrived at a more exact determination of the electro-motive forces, and more complete study of the intervention of electro-capillary actions in the phenomena of life.

Mr. P. Bonham made some remarks on some further experiments on *Crystallisation of Metals by Electricity*, in which he stated that he had placed the positive and negative electrodes of a battery in a vessel containing a mixed solution of copper and zinc, and that with terminals of copper he obtained a good crystallisation proceeding from the negative pole of mixed crystals of copper and zinc, and beyond this, crystals of copper alone. With terminals of zinc he got a mixture of crystals as before, and beyond of zinc, crystals of zinc alone. But if terminals of brass (a compound of zinc and copper) are used, there is a dull crystallisation of zinc across the field. He also observed that with zinc terminals, by increasing the battery power, the crystallisation is broken up; but not so when the terminals are copper or brass, but then the crystallisation extends closer and beyond the positive pole.

Mr. Gladstone read a paper *On Silver Nitrate*, giving the

---

the corresponding current passed. The spokes formed by these squares at 2 were to be illuminated by a great beam of light polarized by reflection from glass, and received again by an analyzer. It is evident that, since the intensity of the analyzed light depends on the position of the plane of polarization by each little square of iron, and since this depends on the strength of the current, and that again on the illumination of the selenium, we have another method of receiving at 1 the illumination of the same square at A. It is probable that Prof. Graham Bell's microphone may admit to some plan of a much simpler kind than either of ours; but in any case it is well to show that the discovery of the light effect on selenium carries with it the principle of a plan for seeing by electricity. JOHN PERRY

Remarkable Electrical Phenomena.

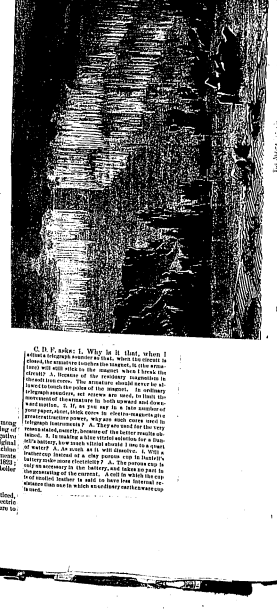
The night of July 7-8, 1835, will be long remembered in Switzerland for thunderstorms, several of them of almost unexampled severity. Of these, one that broke over Geneva was unprecedentedly severe and disastrous. It appears to have originated in no violent, in the department of Ain, and took an easterly course up the valley of the Rhone, over the lake, and through the city of Geneva, without rain, and hence did not elicit the course over Savoy. An oblique course on, though the heat was suffocating and not a breath of wind stirred below on the streets, light objects on the roofs of the houses began to be whirled about and carried off at by a tempest of wind. At the same time a dull, rumbling sound, resembling neither that of wind nor that of thunder, announced the approach of the thunderstorm, and at 11 minutes exactly it burst over Geneva in all its fury. An avalanche of enormous hail stones, with no trace of rain, was precipitated from the sky, and shot against opposite objects by a tempest of wind from the southwest. In a moment the street lamps were extinguished, and in a brief interval incredible damage was inflicted, the glass and tiles of houses smashed to powder, trees stripped of their bark and the side facing the west, and even of every sort were, in many instances, driven into the ground. The smallest of the hailstones were the size of a hard nuts, many were as large as walnuts and chestnuts, and some even as large as a hen's egg. Some of the hailstones measured four inches in diameter, and six hours after they fell weighed upwards of ten ounces. For the most part the hailstones were of a flattish or lenticular form, with a central nucleus of 9 to 12 lines diameter, developed in several concentric layers of ice, generally from 6 to 8 alternately transparent and opaque. A map has been printed in the *Journal de Genève*, showing the districts where the storm was felt, as well as the degree of its intensity in each locality. The electrical phenomena were very remarkable; the flashes of lightning succeeded each other with such rapidity, from midnight till a few minutes after 1 o'clock in the morning, that a mean of from 2 to 3 were counted per second, or from 9,000 to 10,000 per hour. Electrical phenomena were remarkably developed before and during the hail. The ground, almost in prominent objects, as well as the hailstones, were strongly electrified. Immediately after the hail, some was greatly developed, the smell being so pronounced as to be compared, by nearly all observers, to sulfur. The intensity of the electric charges passed from cloud to cloud over a central point from which the hail fell, but thunder was very rarely heard.—*Nature.*

ELECTRICITY.

The old electrical machines are very interesting. Among them will be seen Priestley's electrical machine, consisting of a glass globe which can be rotated on a fixed rod, whose negative electricity being obtained from the rubber; Nairne's original globe and cylinder machine from King's College; a variation of the same by Singer and used by Beccaria in his early experiments in connection with the electric telegraph, described in 1672; and Armstrong's Hydro-electric machine—an old iron boiler standing on glass legs.

THE AURORA.

Prof. Lemström's polar light apparatus should be noticed, intended for showing that the Aurora Borealis is an electric current flowing from the higher regions of the atmosphere to the earth.



Annales de Chimie et de Physique,
August, 1875.

Relations Between Electric and Capillary Phenomena.—M. Gabriel Lippmann.—The following is a resumé (by the author) of this valuable memoir. Two distinct laws have been demonstrated by experiment; the first (chap. i.) connects the capillary constant with the electric difference; the second (chap. ii.) connects the variation of the electric difference with variations of area of the surface. These two laws, established separately by experiment, are connected together by a tie essentially necessary, if we admit the principle of energy and without hypothesis, that is to say, if the two laws formed (three decrits), which is to say, if the second law were assumed, work would be created, if the first law were not assumed. In the mathematical theory of chap. iii. this relation has been established anew, in analytic form; the analysis rests on two principles:—(1), conservation of energy; (2), conservation of quantities of electricity. No hypothesis has been called in, either in this or in the rest of the work; it is to avoid doing so, that I have abstained from giving a physical theory, an explanation of the properties observed. The electro-capillary meter described (chap. iv.) shows directly—(1), that an indefinite quantity of electrical work can be converted into mechanical work by means of capillarity; (2), that the phenomena described above are reversible. If we compare the phenomena with those of thermo-dynamics, we find that the first law answers to the law of dilatation of bodies by heat, and the second to that of cooling during expansion. The first law has also a second consequence, (3), which consists of the identity connecting the measurements of electrical tension (theory, chap. ii.), and measurements of electrical attractive forces. The electrometer described in chap. vi. is much the most precise of the electrometers now known. Chap. vii. contains the explanation of the whirlwinds described by Gerbois. The principle explaining them seems susceptible of some further applications.

SCIENCE IN GERMANY
(From a German Correspondent)

HERR W. SIEMENS has recently made the following communication to the Academy of Sciences of Berlin:—

It has been shown by Willoughby Smith and by Siale that crystalline selenium conducts electricity better when illuminated than when in darkness. The specific conductivity, when platinum and selenium rendered crystalline by heating from 100° to 150° C. is very small and extremely variable; and also the increase of the conductivity through illumination is very inconstant, so that it is impossible to establish a more dependence of the conductivity on the illumination.

I have discovered, however, by continuous heating of amorphous selenium to a temperature of 210°, as also by long continued heating at 180°, and by very long continued heating enclosed, the selenium passes into a coarse-grained crystalline state, in producing another modification of the crystalline selenium, which has considerably greater conductivity, and retains it, and conducts in this state electrically, so that with increase of temperature the conductivity decreases. The action of light on this modification of crystalline selenium is much greater, and apparently quite constant. Bring in two fine spirals of wire, about 1 millimetre apart, between two leaves of mica in coarsely crystalline selenium, he has obtained an exceedingly sensitive measure of light. Dark heat rays are *absolutely without influence* on the conductivity, and heating of the selenium, as already mentioned, *diminishes* the same. Diffuse daylight even doubles the conductivity of this light-measure, and direct sunlight increases it sometimes *more than eightfold*. The increase of conductivity of the coarse-grained selenium through illumination takes place very quickly. And similarly, the diminution of it, on shutting off the light, occurs, as a rule, in a very short, a longer time is required before the state corresponding to darkness is again fully established. The increase of the conductivity is not proportional to the light intensity, but a function of it, which comes near the proportion of the square root of the light intensities.

Herr Siemens hopes this interesting property of selenium may be utilised for construction of a reliable photometer.

...was scarcely will be without its wire.

CAVENDISH showed that nitrogen and oxygen in air formed a mixture only, but that the passage of electric sparks produced their chemical combination—nitric acid being the result.

---

that the tube is open at both ends. We have, however, common experience—such as a thunder-clap, noises caused by the expansion or displacement of free air; and it may be conjectured that when the empty space is made by so rapid a motion as that of sounding, this sort of *electric click* will be produced. If the capillary be enclosed at one end, the phenomenon is reproduced with great facility.

When the platinum wire is restored to the open tube the vapour bubbles formed as in cautiously break the corner; as they condense the liquid is drawn up into the tube to re-fill the empty space thus formed, and rises to the upper portion, whence it falls back again in sparkling flets. Fresh bulbs of vapour re-form and condense, the liquid remounts, and the phenomenon reproduces itself in an intermittent manner.

In the previous experiments the positive wire was in contact with the liquid tube; if this wire be plunged into the liquid without touching the glass, luminous globules (already described) will be animated by a gyratory movement and will be produced. The length of the liquid column is not an obstacle to the production of the globules, as we have seen in the insulating tube of a condenser. When the negative wire is deeply immersed, and the liquid column is also kept strongly negative, the luminous globules formed at the positive pole disappear without sparks as the negative pole, and allow the electricity they enclose to flow into the air or to the surface of the liquid. But, when the negative wire is only slightly immersed, if the positive wire be also immersed its immersed surface is soon found to be greater than that of the negative wire, by the spherical agglomeration of the liquid in its neighbourhood. The current then traverses the voltameter, instead of remaining accumulated at the surface, and the properly called discharge is then produced with a noisy spark, fusion, or volatilisation, of the electrode at the negative pole.

Several conclusions may be drawn from these phenomena, in explanation of the effects of atmospheric electricity.

First of all we meet with representation of various kinds of lightning flashes. The electrified globules formed by the aqueous vesicles of the clouds may be produced or disappear without any explosion, and so give rise to those glimmerings (or flashes without thunder, as are sometimes seen in the still evening sky). Sometimes, We can also understand how electrified globes, observed near the ground, may be luminous without certain explosion, and how, near observers without striking them, may locate themselves on telegraph wires without melting or volatilising them. The phenomenon just described under the name of electric thunder-clap may likewise give the idea of thunder—not that there is in this case a discharge as at the time of the thunder-stroke; but the experiment offers an analysis of the noise which is produced at the time of the cessation of an electrical current moved enough to have previously surfused or volatilised the material opposed to its passage.

The same series of experiments explains the crackling noise of waterspouts; the mist which is formed around them, formed as that which leaves a steam-boiler; the silent flashes which rend them; the fire-balls at their extremity; and the bubbling agitation of the waters when they touch the surface of the sea. These meteors may be compared to positive liquid or vapour electrodes from which the powerful electric currents of storm-clouds escape towards the land or sea; and, if they are not accompanied with fulminating effects, it is because the conducting cloud accompanies them to the earth, and because there is not in that case a properly called electric discharge, any more than in our experiments. The conical form of waterspouts can be explained by the tendency of positive electricity to form cones in the air, under certain conditions, as to their gyratory motion, though the electric flow seems to produce by itself whirling effects, mechanical actions may also account for them; and we can only affirm

M. Plantè is at present engaged in researches on the phenomena produced by currents of high tension by means of his secondary battery, and the results seem likely to throw some light on a number of natural phenomena (those of thunderstorms, terrestrial polar auroræ, &c.) In one experiment described, having inserted the positive platinum wire in a capillary tube and this in a liquid, a stream of mist occurred; and on taking the arrangement out of the liquid there was a detonation like that of a fulminating capsule. The tube was neither broken nor heated, but the lower extremity had become conical like the top of a funnel. The phenomenon is purely mechanical—due to sudden entrance of air into the tube. The intensity of the sound, M. Plantè says, is remarkable, considering the narrowness of the annular space between the wire and the sides of the tube, and that the tube was open at both ends. But, he adds, there are other examples, such as the crack of a whip, of sound imposed by sudden displacement of free air, and we may suppose that, a vacuum having been produced by the rapid passage of electricity, such air rushed to fill the tract occurred. Something similar may take place in the case of thunder—in the sudden creation of the electric effect.

Effect of Magnetism on Watches.

To the Editor of the Scientific American: Oct. 7 5

A few weeks ago my watch, for the first time in ten years, refused to go. Up to then, it had kept correct time, and was then in good repair, having been recently cleaned. When it first began to stop I would start it by the key, and it would sometimes run a day; but finally it stopped entirely. I had it carefully examined by an expert, who, although he could find no cause, failed to make it run even for an hour.

I was running at my works a powerful magneto-electric machine for depositing copper; and having noticed that I could magnetize a piece of soft iron at a distance of at least six feet from the machine, so that it would lift and support the weight of a large nail, I became impressed with the idea that some of the steel parts of my watch had become permanently magnetized; so I made a watch repairer take it apart. Having some fine soft iron filings, I dipped the balance wheel, escapement wheel, lever, and hair spring into the filings; and each piece raised up at least one half inch with weight of the filings, through the polar magnetism of the particles.

I have read of watches being spoiled by magnets, but had no idea that it was unsafe to go into a room containing a magnet.

The watchmaker thought he might "break it off" for about a dollar: I let him break on it three days as a lesson in magnetism, and then told him that nothing short of heat, like it red hot would demagnetize it. He put in new parts, including a new mainspring, which was also infected, and the watch now runs as well as ever.

Remarkable Electrical Phenomenon.

The night of July 7-8, 1875, will be long remembered in Switzerland for thunderstorms, several of them of almost unexampled severity. Of these, one that broke over Geneva was unprecedentedly severe and illustrious. It appears to have originated to westward, in the department of Ain, and took an easterly course up the valley of the Rhone to Geneva, on reaching which it spread over a wider area, and thence directed its course over Savoy. As midnight came on, though the heat was suffocating and not a breath of wind stirred below on the streets, light objects on the roofs of the houses began to be whirled about and carried off as by a tempest of wind. At the same time a dull rumbling sound, resembling neither that of wind nor that of thunder, announced the approach of the thunderstorm, and at 12 midnight exactly it burst over Geneva in all its fury. An avalanche of enormous volumes, with an mass of rain, was pre-eminent from the sky, and shot against opposing objects by a tempest of wind from the southwest. In a moment the street lamps were extinguished, and in a brief interval incredible damage was inflicted, the glass and tiles of houses smashed to powder, trees stripped of their bark on the side facing the west, and crops of every sort were, in many places, all but totally destroyed. The smallest of the hailstones were the size of hazel nuts, many were as large as walnuts and chestnuts, and some even as large as a hen's egg. Some of the hailstones measured four inches in diameter, and six hours after they fell weighed upwards of 10 ozs. For the most part the hail stones were of a flinty or lenticular form, with a central nucleus of 9-16 to 9-10 inch diameter, developed in several concentric layers of ice, generally from 8 to 8 alternately transparent and opaque. A map has been printed in the *Journal de Genève*, showing the districts where the storm was felt as well as the degree of its intensity in each locality. The electrical phenomena were very remarkable; the flashes of lightning succeeded each other with such rapidity, from midnight till a few minutes after 1 o'clock in the morning, that a mean of from 2 to 3 were counted each second, or from 6,000 to 10,000 per hour. Electrical phosphorescence was remarkably intense before and during the hail. The ground, animals, prominent objects, as well as the hail stones, were strongly phosphorescent. Immediately after the hail, stones was greatly developed, the hail being so pronounced as to be recognized, by nearly all observers, to garlic. The incessant electrical discharges passed from cloud to cloud over a central point from which the hail fell, but thunder was very rarely heard.—*Nature.*

The Remarkable Electric Phenomenon.

To the Editor of the Scientific American: Sept 25

Regarding the statements relating- to the singular electric phenomena described on pages 193 of your current volume, as being in some respects opposed to hitherto observed facts, I decided to investigate the case thoroughly, and ascertain in the first place what the facts were, and then see whether they were in accord with previous observations. For this purpose, I sent one of my assistants to the house where the electrical displays occurred, furnished with the proper instruments for making careful and accurate measurements of the resistances of the rods, pipes, and other conductors about the premises.

The first measurement taken was to ascertain the resistance between the two pipes leading to and from the Waterworks. This was found to be less than 0.01 of an ohm, and most of that was probably due to the connections of the galvanometer. Of course this proved conclusively that no sparks ever passed between these pipes, and Mr. Baldwin, the occupant of the house, said that the published statement was wrong in this regard.

The resistances of the supply pipe, overflow pipe, waste pipe, and lightning rod were then measured, with the following results: Resistance of the lightning rod = 181 ohms; of waste pipe = 284 ohms; of overflow pipe = 15 ohms; of supply pipe = 0. The house stands on a hill on the dividing line of a slate and limestone formation, and the lightning rod has been placed in the form of the rock to the depth of, perhaps 6 or 7 feet, and is therefore partially insulated; and its normal resistance is doubtless much more than 181 ohms, which was found while everything was wet, a resistance having come up just before the tests were made. A resistance of 181 ohms in the lightning conductor, is sufficient, in my opinion, to occasion all the phenomena of discharge which have been observed during heavy storms. The waste pipe runs in iron, and leads off to a spring half a mile distant, where the best earth connection in the country is found. Owing to the insulating quality of the foundation upon which the house rests, the house constitutes one side of a leaky condenser, of which the slate and limestone form the dielectric, and the earth the opposite side. When a thunderstorm occurs, the whole house is charged in a greater or less degree; and as the only connection of the lightning rod is insufficient to carry all the electricity which it receives, the electricity is discharged through every available channel, of which the supply pipe is the best. In light storms, the phenomenon would not be noticed; it becomes very marked in heavy ones.

In this case the supply pipe was the safety valve of the house. The proprietor of the house was advised to connect the lightning rod to the supply pipe by a large copper wire, which will probably terminate the curious phenomena which have been observed.

I trust the time will soon come when lightning rods will be erected by persons possessed of sufficient electrical education as to be able to tell whether they have a resistance of 181 ohms or of 0. Probably no important business at the present time, is as a rule entrusted to a class of men so utterly ignorant of their duties as this one. In every case where a building supplied with a lightning rod is destroyed by lightning, the parties who put up the lightning rod ought to be prosecuted. A rigorous course of treatment of this sort would soon convince these people that a reasonable amount of study of the laws of electricity is necessary for their own safety as well as that of their patrons.

I wish that every electrical phenomenon which occurs could be promptly and carefully investigated by competent, practical electricians. Why cannot the scientific departments of our colleges undertake this service? It would furnish a fund of accurate information which would prove of very great practical value.

New York city. GEORGE B. PRESCOTT.

Anomalous Behavior of Selenium.

It has been lately observed that the electrical resistance of selenium is greater in the light than in the dark. It was at first thought possible that this increase of resistance might be due to heat combined with the light, but Prof. W. G. Adams, in his paper read before the Royal Society, June 17th, 1875, has shown that this is not the case, but that the phenomenon is a purely optical one.

The writer of this letter has to-day tried an experiment with a selenium bar belonging to the Cavendish Laboratory. Its length is 50 mm., breadth 8mm., thickness about 1mm.; platinum wires are soldered to its ends, and it has a hard metallic surface. Its electrical resistance is enormous. In the dark it is just over 100 megohms (100,000,000 B. A. U). When, however, the light of the prafts lamp of the galvanometer was allowed to fall on it from the distance of about a foot, the resistance dropped between 20 and 30 per cent. The experiment was repeated many times, with current now sometimes one way, sometimes another, and with different sides and edges of the bar turned to the light, but always with the same result, namely, that the effect of letting in the light was to largely decrease the resistance.

A second set of experiments was made with a selenium medal struck by Berzelius soon after the discovery of the metal in 1818, and presented by him to Mr. Dark, by whom son, Mr. Dark of Cambridge, it was kindly lent for the experiment. This medal was of circular shape, about 40 millims. long by 30 broad. Owing to the difference of form between the two specimens, their specific resistances could not be accurately compared; that of the medal was, however, not more than about 1-10 of that of the bar. The medal was exactly like black lead both to touch and sight, and quite different in appearance to the bar. The resistance of the medal was sensibly *the same, both in the dark and in the light: no difference could be detected.*

The experiments seem to show that the physical form of the metal has a great deal to do with its behavior when carrying an electric current and exposed to light.

Aniline Black by Electricity.

It we take a strong solution of sulphate of aniline and anilenic it to the action of two Bunsen elements, employing platinum electrodes, we soon see the positive pole become coated with a violent blue covering, gre-nish in places, a fact remarked by Letieby. If the experiment is prolonged for 12 or 24 hours, we find fixed to the positive pole a black mass, easily detached. On treating this substance with ether and alcohol, and drying it, there remains a amorphous black body with some greenish reflections, insoluble in most solvents. If this body is treated with sulphuric acid, and spread out upon a p rcelain saucer, it takes a greenish coloration, but on treatment with alkalies it resumes its jet black color. It is not affected by nascent hydrogen. To ascertain that the production of this black was due to nascent hydrogen, and not to the platinum employed as electrode, I made use of electrodes of gas-coke, and obtained in 12 to 24 hours identical results; a black adhesive mass was fixed to the carbon of the positive pole. Nitrate of aniline gave also a black deposit, which, on treatment with alkalies, took a velvet like appearance; but in presence of sulphuric acid a decomposition took place, and I obtained a brown mercury coloration. The composition of this black is, therefore, different from that obtained with aniline salts. Metals of aniline gave, around the positive pole, a black cuoghlon but it is probable that, in this case, the action is complicated, and that there may be at the positive pole, besides nascent oxygen nascent chlorine, which complicates the results.

With the organic salts I have obtained differences which require notice. Aniline acetate gave, at the positive pole, a black glutinous substance, partly soluble in the surrounding salt. Aniline tartar gave, as result, not even the least coloration of the positive pole. Hence it appears that aniline blacks may be obtained without the intervention of metals, and that the salts of aniline behave in different manners with the nascent oxygen.—*J. J. Coquillon, in Comptes Rendus.*

1875

Some important researches in the flow of mercury in capillary tubes and the electric phenomena which accompany them, are described in a recent paper by Mr. Hockin, Assistant Professor of Physics. He considers especially the influence of metallic contact, on the efficiencies, by comparison, of the capillary tubes employed in the experiments. Spring demonstrates: formation of drops of mercury of electricity through capillary tubes, and stoppage of flowing from friction of the liquid against the tube. Also, that from thermo-electric currents in the drop. An electric current *favoring* the liquid column from the exterior to the interior, increases the quantity of mercury which flows out, while an opposite current diminishes it. Also, that simultaneous currents retarding in the flow. M. Gore thinks this is because the electricity of different elements employed to saturate the conditions of the atmosphere has been in contact with metallic tubes through capillary tubes, and elsewhere in the drop. M. Spring's investigation seems to throw a good deal of light on the nature of molecular action.

MOTIONS PRODUCED IN MERCURY BY ELECTRICITY.

In the spring of 1853, the attention of the late Sir Charles Wheatstone was directed to the discovery of Ersman (1809), that a globule of mercury in contact with an electrolytic liquid within a tube of small calibre moved forward when a current of electricity was passed through it. Sir C. Wheatstone patented a form of telegraph-receiving instrument depending on this principle. Mr. Robert Sabine has been making some interesting experiments in connection with this instrument (*Phil. Mag. Suppl.*, December, 1876), and has been led to assign to the experiment cited above, and to others of a similar nature, an explanation different from that which has been usually accepted. This explanation is based on the observed fact that a mercurial surface, when exposed to the influence of air or of water, consists of mercurous oxide, and not of metallic mercury, that the electropositive condition of a mercury surface is greatly dependent upon the state of oxidation, that the expansion or contraction of such a surface is always attended with a corresponding alteration of the electro-positiveness, and, finally, that the motion of mercury cl e cooles under water (gas or solidified) are principally due to the reduction of superficial oxide. An ordinary U tube had mercury poured into the bend, to about an inch up each limb; acid water covered the mercury surfaces, and platinum wire, connected with a galvanometer, were inserted in the water. When the tube was tilted, the needle of the galvanometer showed a deflection, whose direction was reversed when the tube was tilted the opposite way. The electricity thus produced was due to the advancing surface of the mercury becoming brighter—unoxidized portions breaking through to the front—and, consequently, more electro-positive than the receding surface, which became duller. In his paper on the connection between volcanic and electrical phenomena (*Phil. Mag.* [iv.] xlviii. p. 249), M. Lippmann ascribed the electricity, which he observed to be produced when a mercury surface into water advanced, to a similar cause, to a change in its capillary constant. Mr. Sabine's experiments show that this explanation may be accounted for by different amount of oxidation of the advancing and receding surfaces. When a current of electricity is passed through a horizontal tube containing water or dilute sulphuric acid, with a globule of mercury in the centre, the globule is seen to move in the direction of the current. This arrangement constitutes, in fact, practically Lippmann's capillary electrometer, and its action is explained by its author as being due to a change of the surface tension of the mercury as its two ends, where oxygen and hydrogen are respectively evolved. According to Mr. Sabine, capillarity has very little to do with the phenomenon, which is to be ascribed to the chemical changes taking place in the mercury globule. At the electrified end its atomic volume diminishes, but increases at the oxidized end, where, in consequence, a relative expansion takes place. Circulation of the mercury particles ensues, and if the tube be horizontal the globule marches with the current. A number of experiments are adduced in favor of this view. Mr. Sabine, however, probably depreciates too much the effect of capillarity.

to be lighted up after the shocks." December 27th, N. K. Italy: "At Parma a sudden light, loud clap of thunder;" night between 26th and 27th, "at Genoa, in the midst of a terrible storm." 1847, March 11th, E., Valley of Chamouni and at St. Gervias: "lightning was of several over Mont Blanc, and a sort of light on the snow-clad side of the valley." 1854, Jan. 7, Perugia: "Flashes of the whole sky." 1854, *A storm* which I regard this day over Pescara, Marseilles, Savona, and Northwest of Var: at Amiliau (Var) "the weather had been very rough; at a few minutes past 7 p.m. a rush of the subterranean noise was then heard, and the shock took place. The wind then rose, and the storm raged as before." 1822, February 19th, E., S. of France and Switzerland: "violent turbulence of the surface of the lake." 1854, September 9th, E., Sicily: "a loud noise like that of waggons, but interrupted." 1854, until the thunder was heard; and, although the air was perfectly calm, the trees, grass, &c., were found to have been blown about as if by a whirlwind. At Ven Hoff recently, it is very doubtful whether this took place. It is very earthquake phenomena." 1854, November 11th, E., Sweden: "shortly after December 27th, August. The shock was not at all felt at the bottom of the mines, but those who were on the ladders of the same were so shaken that they let go the ladders were about to fall." 1854, December 13th, E., Bellay, Department of Ain: "a violent shock, followed by a great ing-place of meteors." 1854, January 1st, E., Sauges, Var: "was on the day of a fall of the size of a man's fist, reported that the heavens appeared to take all on fire at instant after the explosion, although he saw nothing." 1854, December 17th, E., Venezuela, M. Codallo says, regarding the earthquakes in Venezuela, that "great irregularity generally exists in the appearance of these shocks, and often no correspondence can be traced between them at places very near each other." 1829, March 8th, E., Siberia: "at Kiachta and Troitzkosawsk, a noise like that of a violent fall of wind in a storm. At Irkutsk a clattering noise, as a discharge of musketry, was heard by all, whence Dr. Erman concludes that it was not a subterranean but atmospheric phenomenon." 1829, February 8, Valley of Bartaisk, Sardinia: "a tremendous explosion which was overwhelming. Animals and vegetables, too, were killed." 1829, January 8th, E., Bengal, "accompanied by a noise which seemed to be on the surface of the earth and immediately beneath it, like that of the firing of cannon, and also like that of thunder." In another place a crackling noise is heard in the air." 1829, October 24th, E., at Concon—no sure day magnetic perturbation. At Chili, on the next day at Concon, Parral, Brussels, Milan, Naples, Perugia, and St. Helena. December 19th, E., Baden: magnetic perturbations on the 19th and 20th. At Paris, Brussels, Rome, Prague, and Milan. On the 18th and 19th a remarkable fall of the barometer at Paris. During the night of the 20th-20th an aurora borealis at Concon.

But we must not intrude further upon our Editor's space. The cases which the reader will find in E. Mallet's and Perrey's catalogues of earthquakes, Herschel's "Aerial World," publications—not omitting a notable case in the Bostonian Repository of the middle ages, and of the development of electricity in mountains during storms.

ELECTRO-MOTIVE CHANGES PRODUCED BY LIGHT.

PROFESSOR DEWAR, of Cambridge, gave the "Friday evening discourse" at the Royal Institution on the subject being the "Physiological Action of Light." He first referred to the experiments of Du Bois-Reymond, who found that strong muscular movements of the arm and leg produced changes in electrical condition which could be easily detected by a galvanometer. We know now the Sir W. Thomson's reflecting galvanometer, a much more delicate instrument, and it occurred to Professor Dewar that it might be possible, in this fact which must more delicate changes than Du Bois-Reymond could. He observed, by having two wrangles connected with the galvanometer and containing saline solution, that putting one hand in each, the mere muscular effort of shunting the fluid caused a difference in the amount of the electric current. Other experiments also showed how readily the slightest electrical or electro-motive force could be in this way detected. It had occurred to him that the test might be applied to the excitation of the external organs of sense, especially with regard to the eye. Professor Dewar then proceeded to explain the way in which the experiments on eyes of different animals were effected. The eye, on being removed from a recently killed animal (the rabbit and guinea pigs were used) is placed between two little supporting cloth pads are called electrodes, and are then connected; these are in two little troughs, made of zinc, mounted on vulcanite plates and carefully amalgamated. A small glass tube, drawn out to a point, is nearly filled with fine clay, and this is placed on the cornea, the amalgam of zinc coming some little distance up the tube, and the ends of the tubes present any minute clay points. The object of this is to protect the animal structures from the irritating effects of the solution of sulphate of zinc. These electrodes are to be regarded simply as an arrangement for collecting and conducting off electrical currents from the structures under examination. Wires are connected from the troughs with the galvanometer, arranged so that the current can be cut off or put on at any moment. This arrangement is now found exceedingly free for the examination of the eyes of living animals as well as of those recently killed. In the case of animals just killed, the eye is recently removed as skillfully placed between the two clay points of the electrodes, and then the moment the connection is made with the galvanometer a mirror is made to swing round, indicating the presence of an electric current. If, on a short time the reflection will settle down at some fixed point on the scale, and this amount of deflection will indicate the amount of electric current passing in the cornea or the cornea-sclerotic section of the eyes. Since almost every variety of living animal has been shown to electrical current when examined in this way, it became an important question to see how much of the action lay on the side of light. The test this is to easy to put the eyes with the electrodes under the microscope, and with white light on them. This was allowed for the oscillating reflection on the mirror to settle, the indicating the natural electric current of the eye. The needle of the galvanometer at a fixed position. Light was then allowed to fall on the eye, and a diminution of current in the eye as the reflection of the galvanometer needle indicated a change in the electric condition of the eye produced by the light. The next question to be solved was whether this action occurs in only particular part of the eye. To test this, the cornea of the eye is cut away and one of the clay points brought in contact with the retina. This is an important point, as the electrical changes produced by the action of light might be supposed to be due to the contraction of the iris, the pink bulge of muscular structure contracting on the action of light in a well known reflex mechanism in normal circumstances, and even after the removal of the eye from the head. A contraction of the iris might produce a negative variation of the electric current. This is why it is removed. The action observed coincided with that of the complete eye. The current is affected when light shines on the retina. Still further experiments, that of flashing on the retina and leaving only the sclerotic, showed that little or no current was obtained, it was not affected by light. Therefore it seems certain that the variation produced by the action of light is due to some change which light affects in the retina. In experiments so far mentioned were, of course, made on eyes taken from recently killed animals, and up till lately there have been difficulties in experimenting in warm-blooded animals, as long as the nerves and the eyes also after removed from the body. Professor Dewar has, however, found that by placing an eye-ball in such a position that some saline solution can be put on the optic nerve, and placing on this solution one of the electrodes, with another electrode on another part of the body, successful experiments can be made. He has had the experiments tried on himself, so that there can, he explained, be no severe charge of cruelty to animals in experimenting on living rabbits, cats, lobatues, etc., as he has. The general conclusions arrived at are in accordance with those made on eyes recently removed from dead animals. Considerable difference is noticed whether the light brought near the eye is fixed or moved about. A light was arranged to oscillate by suspension, and the amount of deflection produced on the scale is far in excess of that

when Hertz. Just care was taken, as far as possible, to ascertain that heat had nothing to do with this action. Professor Dewar then went on to speak of experiments on the time occupied in a nervous sensation. The instrument used was the chronograph of Hipp mith, made by Hardy, of Paris. It consists of a large tuning-fork, giving 200 vibrations a second, fitted up so that the vibrations can be recorded on a blackened cylinder by an electro-magnetic apparatus. A stylette is placed at one end of the tuning-fork, and on a level with this is a strip of blackened paper, pulled down gradually by pulleys, and so arranged that the stylette can mark on it. Each vibration of the fork indicates the 1/200 part of a second. With the stylette, in another electrical apparatus, consisting of an electro-magnet, the passing of a current of which carries a marker. As a current passes the marker descends, making a mark on the blackened paper. It is arranged so that one of these makers signals at the moment the impulse is sent out; the other, under the eye of the observer, signals directly the reflection of the impulse sent to the screen. The position of these marks, with reference to the vibrations traced by the fork on the area of the tuning-fork, gives the interval of time. It was found that with a candle-flame as a stimulus, 1/5 of a second. This, however, includes also the time the observer took to see the phenomenon and record it, and in the end time elapsing between the admission of light and the change in electric condition is less than this. Experiments show that there is an alteration in the excitatory function by continued action of light, and this is, no doubt, the physical explanation of what, in physiological language, is called fatigue. A number of tables showing the rate of fatigue were exhibited.

EFFECT OF ELECTRICITY ON PARTICLES SUSPENDED IN LIQUIDS.

The Lancet, June 18/6

Some interesting observations on electricity have recently been described by M. Holtz in Poggendorf's Annalen. A "vehicle" of particles suspended in a liquid, when submitted to electric currents, has been known of, and was fully studied by M. Quincke. M. Holtz finds that in all cases of such motion, there is at the same time a clinging of particles to one of the poles, and this often with such precision that one might construct an electroscope on this principle for ascertaining the polarity. Especially notable is the tendency of *Semen Lycopodii* in insulating liquids, particularly sulphuric ether, to cover the negative pole with a thick coating, while sulphur, cinnabar or sulphide of antimony in the same liquid, only coat the positive pole. A simple medicine glass even suffices for the experiments; a conductor or half conductor being introduced through the stopper. The glass is held in the hand, and the conductor pushed down into the liquid. The two poles of a Bunsen battery may be used.

M. Holtz did not, like Dingenen and Quincke, use capillary tubes, but hide vessels, and this, he thinks, maybe the reason why many substances, e.g., sand, manganese, sugar, &c., seemed to be quite indifferent, neither wandering nor adhering to the poles. But here occurred another interesting phenomenon. If a portion of the vessel was left straight and smooth, and not rendered conducting by a layer of moisture condensed from the air, or by the particles formed figures, under the action of the electric current, of various characters according to their size and structure, and according to their own conductivity or that of the liquid. Figures of extraordinary liveliness and regularity, and quite corresponding to those assumed by iron filings under action of the magnetic poles, were obtained with finely wandering ear-shaped, wavy, and nodic al lines, in petroleum, oil of turpentine, benzine, and sulphuric ether. Still finer, and consisting of largely entwined lines, were the figures formed under reduced iron; but extremely little of this substance must be used, owing to its great conductivity. The figures formed of sawdust were more regular, and branching like trees. Cinnabar in ether gave a cloud-like form which, on account of the polarity referred to, surrounded the positive pole. Sugar and bran mostly formed thick connected skeins, through which the electricity then flowed as by a conducting bridge.

In very few cases, however, is the figure stable during the electric action. In general, while the figure does not essentially alter in character, one may readily distinguish in it a double movement, first a threating to and fro of the separate particles within the lines; they form (and this motion is stronger the larger the particles and the smoother their surface); then a continuous displacement of entire lines vertically to the connecting line of the poles, and this apparently more outwards if the electric current is strong, more inwards if it is weak. This latter motion, however, frequently becomes of a rotatory character, the connecting lines sometimes breaking, and each part for itself tending to circle round the pole to which it adheres. Such circular motion occurs in greater measure with cinnabar, sulphide of antimony, and some other matters, which generally do not form connected lines. It appears in a peculiar halting together and gliding forward of separate parts.

But the circular movement is greatly favoured if a wire ring be taken for one pole, and the other pole be placed in the centre of it. In this case, naturally, the external form of the figures is altered, and in most instances, whatever the polarity of the central conductor, one obtains figures which in their radiating structure resemble the Lichtenberg figures. With those materials which do not connect themselves in lines, the circular motion now becomes so distinctly the prevailing one, that the figures produced fully correspond to the negative Lichtenberg figures.

The remarkable phenomenon was best obtained in a glass zoometer, with high and nonconic diameter, having a perfectly even and smooth bottom, and which had not been used for previous experiments. In the axis was fixed a wire which, with its lower point, touched the middle of the bottom, and this glass vessel standing on a conducting basal was slowly and constantly electrified with one pole of an influence machine. M. Holtz describes in detail the effects obtained when this vessel was charged after the fashion of a Leyden jar.

Another but similar phenomenon in some of the above experiments was the formation and rise of the liquid on the insulated wires. This takes place to greatest degree on the negative wire, and with sulphuric ether it is intimately connected with the polarity of the surrounding particles, for through adhesion of these to the one pole the rise of the liquid on the other pole is favoured. M. Holtz hopes to study the phenomenon further.

MUSCULAR contraction, it is known, is always accompanied with electric phenomena; the difference of electric potential between two points of a muscle, undergoes a diminution, which according to Bernstein, precedes by about 1/10 of a second, the contraction of the muscle. This *electrical negative bar* has been observed on various muscles, and in particular on the heart (by Du Bois Reymond and Kölliker), and recently M. Marey has represented it graphically by photographing the indications of a Lippmann capillary electrometer. We learn from the *Journal de Physique*, that M. De la Roche has tried the experiment on the heart of a living man. The points of the epidermis of the chest were connected with the poles of a capillary electrometer, by means of electrodes, formed each of a bar of amalgamated zinc, with a plug of muslin at its lower end saturated with solution of zinc. Held with insulating handles, the bars were applied, one with its plug opposite the point of the heart, under the left nipple, and the other to another point of the chest. The mercurial column was then seen to execute a series of very distinct periodical pulsations synchronous with the pulse (each pulsation even marked the double movement of the heart (of the auricles and ventricles). The amplitude corresponded to about 1/200 Daniell.

Nature, 77

ACTION OF LIGHT ON SELENIUM.

LAST Friday week Mr. C. W. Siemens, D.C.L., gave, at the Royal Institution of Great Britain, the "Friday evening discourse" on the action of light on selenium. Mr. Siemens said that the influence of light on selenium makes itself known as an action which regulates the extent of an electrical conductor. Mr. May, a telegraph engineer at Valentia, noticed that a selenium resistance was required, offered considerably less resistance to a current when exposed to light than when kept in the dark. The facts were made known by Mr. Willoughby Jones in 1873, but these for a while the matter rested. The statement was received with great incredulity. Could it be that under the same superficial action of light upon a solid substance could so change its electric condition as to open among its particles floodgates for the passage of the electric current, or, again, close them? Again and again, in the interval of the last twelve months, have we had the matter of independent inquiry by Dr. Werner Siemens in Berlin, which agree in most points of fact, though they somewhat differ in the deductions they draw from them. Selenium, an elementary body discovered by Berzelius in 1817, is placed by chemists in the group termed by them metals and metalloids, and it does not seem to be amenable to the laws governing either of these natural groups. Instead of reduced it presents a known amorphous mass of considerable fracture, which is a non-conductor of electricity, but if a stick of this amorphous selenium is exposed for some time to the heat of boiling water it assumes a crystalline fracture, and when again tested in the galvanometer circuit it is found to be a conductor of electricity. Some experiments were shown of the action of light by a question of time. Werner Siemens, in which the duce its resistance effect. Two spirals of thin wire (iron or platinum) are wound on a glass rod in such a way that the wires be parallel to one another without touching. While in this position a drop of fluid selenium is made to fall upon the plate, filling the interstices between the wires, and to give fineness to the whole. The two protruding ends of the spirals serve to insert the platinum arrangement is no larger than a sixpence. Its action was shown in this way:—It was placed in a galvanic circle, at one time in Daniell's cell, and at the other a dissimilar series galvanometer, though—no movement of the needle was taken that had been kept in boiling water for an hour, and but as soon as the light was admitted the index registered a great passage of electricity. Another disc heated to 210 deg. C., and allowed to cool was then used, and a greater action still was apparent with this. Dr. Werner Siemens has worked at the meaning of this, but without tables and diagrams it is not possible to give an adequate idea of his results. The basis of the change in conductivity seems to be in the degree to which the selenium is heated, for when again allowed to cool its behaviour depends on the degree to which it has been heated. The experiment was shown of the effect of different parts of the spectrum on a selenium photometer was shown, and the difference increases as we approach the violet rays. The effect of two lights in affecting the conditions for the passage of electricity. At the end of the lecture a beautiful but interesting little apparatus was put at work, which Mr. Siemens calls a selenium cell, a small hollow ball, with two apertures opposite to each other. In one is placed a small lens, in the other a mirror, and at the centre is a "stalk." The disc is connected with a galvanometer, and this represents the retina. There are two slides which represent the eyelids. The action of light on the disc is indicated on the galvanometer. Not only was this shown to be sensitive to white light, but sensitive in different degrees to different colours. Mr. Siemens suggested it would be useful in the contact and electro-magnet in connection with the galvanometer in such a manner that a powerful action of light would cause the automatic closing of the eyelids, and have the effect of instantaneously train action of blinding the reader in consequence of a flash of light. To physiologists this analogy may be suggestive regarding the important natural functions of the human frame.

31. Sur quelques effets mécaniques de l'électricité statique, par E. Mach et J. Wosykes. (Ann. de Poggendorff, vol. CLVI, page 407).

Ces quatre auteurs, poursuivant de différents auteurs, traitent du même sujet. Il s'agit de reproduire sur une plaque de verre qui est couverte d'une couche de noir de fumée les étincelles électriques qui se produisent, soit par une machine de Holtz ou une bobine d'induction, soit de toute autre manière. MM. Mach et Wosyka sont de l'opinion que ces images sur le verre noirci ne sont pas les véritables images des étincelles qui les ont produites, mais les effets d'une force mécanique de l'électricité. Cette opinion est appuyée par les résultats de plusieurs expériences.

Notes. 33

As instance of the somewhat rare phenomenon of lightning in a clear sky has been described to a scientific society in Dresden, by Dr. Roch, of Senftenberg. In the early days of July there has been a good deal of thunder and lightning. On the afternoon of the 4th the sky overhead was quite clear, and only a few heavy thunderclouds rested on the horizon in the W., S.W., and N.E. About four o'clock Dr. Roch, with some friends, was walking in the garden, enjoying the fresh air. They were able to count 13-15 seconds between each flash and peal from the distance. Suddenly, just above them, a brilliant, loud-crackling flash passed through the heavens, from N.W. to S.E., throwing the company into some alarm. It was a justification of the poet's line: "Auch aus entwölkter Höhe kann der sündende Donner schlagen." It is notable, further, that, after this flash, there was no more of the distant lightning and thunder. The heavy clouds soon retired, and the sky was once more clear throughout.

We are glad to observe that the lightning-conductors of our countrymen, Messrs. Sanderson and Procter, have gained a medal at the Brussels Exhibition, and that M. Michel, Secretary of the French Committee for lightning-conductors, has commended the system "*comme le plus fonctionnel que je connaisse.*"

A NEW ELECTRIC REPULSION AND ITS APPLICATION TO THE THERMO-MOTOR.

When the finger or a conductor of any kind is brought near to the luminous medium produced in a Geissler's tube, we observe an attraction, which is explained by the known laws of electric induction. But M. Heilriegel and D'Ursulaire (by *Comptes Rendus*), discover that this attraction is converted into a repulsion when the introduction of the gas in the tube is pushed beyond a certain limit. By operating with a number of gases, they found between two points 8 mm. and 2 mm. the known at particles. In continuing the observation, a neutral point was reached, at which there was neither attraction nor repulsion; after which the same gases exhibited repulsion as pronounced as was the attraction. It may be observed at a distance of six centimetres, but does not manifest itself when an insulator instead of a conductor is approached. The authors apply this observation to explain the repulsion of comets' tails by the sun.

INFLUENCE OF LIGHT AND HEAT ON SELENIUM.

Paper, W. G. ADAMS, lately gave before the Physical Society, London,an account of some researches on which he has been engaged, on the selenium with the influence of light and heat upon its electrical conductivity at ordinary and exhibited numerous experiments in illustration. The subject has also been studied by Lieut. Sale and Dr. W. Siemens of Berlin, and as a general result it is found that after it has been kept in the dark, the resistance of the metal is diminished by exposure to light. The effect, however, both of heat and light, is different in the several states through which the metal passes. Thus when a piece of amorphous selenium is gradually heated to about 100 C., kept at that temperature and slowly cooled, its resistance at first is so great that it can not be measured by the ordinary arrangement, but as its temperature increases, the resistance diminishes and increases again more slowly when the metal is allowed to cool. The resistance of several pieces which at the higher temperature were from one to three megohms was found to be from 100 to 150 at the ordinary temperature. If this selenium be placed in a paraffin bath and heated, its resistance diminishes, and when the temperature is kept constant above 140° C. for some hours and the metal is then slowly cooled, it assumes a crystalline structure, and its resistance diminishes as it cools. The resistance of such crystals at ordinary temperatures increases with the temperature. Light also diminishes the resistance of the crystalline bath in some cases. In applying the effect of light, the metal which had been kept in the dark was exposed to a candle at distances of 4, and 1 metre ; the initial resistance being 110,000 ohms. The readings in these three cases were 112,000, 102,500, and 101,500. Reducing each from the initial number we have 2500, 6800, and 8500 ohms as the changes of resistance due to exposure at these distances. Hence the effect of light varies inversely as the distance, or, what amounts to the same thing, directly as the square root of the illuminating power. These considerations have led Prof. Adams to suggest the use of selenium for comparing the illuminating powers of different sources of light, and he exhibited the arrangement which he proposes to use for this purpose. The actions of light of different degrees of refrangibility was then exhibited, by allowing the light from several parts of a spectrum of the electric lamp produced by a bisulphide of carbon prism to fall on the metal, the remainder being cut off by means of a screen, in which there was a narrow slit. The violet, blue, green and yellow, and next two divisions of the screen, the green and yellow, the orange red five and a half, and the deep red nine and a half. The effects were tried by the greenish yellow and the orange. The rays are at times nearly equal. It may easily be shown by the same temperature that the metal that the effect of light on its conductivity is essentially the same in kind at a low and moderately high temperature. The fact that light and non-dark heat produces the observed effect has been shown by recalling the beautiful experiment of Sellme by the bisulphide of carbon. A very small effect on the metal was always observed, but this may be assumed to have been due to light, as it all ceases to be possible to recite the form of the carbon passes through the solution. This fact may be strikingly shown by experimenting with prisms through which a current is passing to the flame of a Bunsen burner, first when in its ordinary condition, and afterwards with the air openings at the base closed. It was shown that, whereas in the first case the effect produced was equivalent to three divisions of the scale, in the latter case one-tenth of the current produced by the exposure deflects the needle to the end of the scale. Prof. Johnstone Stoney then explained the theory which he has suggested in explanation of the phenomena observed in the radiometer of Mr. Crookes, which has been published in the *Philosophical Magazine* for the current month. The theory rests on the supposition that there is an excessively small trace of residual gas in the spheres in which the moving discs are enclosed. When the apparatus is exposed to heat the illuminated side of the disc is slightly warmed, and this warms a layer of air in contact with it. At the ordinary atmospheric pressure, Prof. Stoney assumes the layer so warmed to have the thickness of a sheet of paper, when the temperature of the disc is 59° C. shows that of the resulting air, based on such a supposition we may calculate that the thickness would increase inversely as the square of the pressure the thickness varies inversely as the pressure raised to the power 1. Thus if the disc is exposed to the above the surrounding air, and the exhaustion carried to the twiglith of an atmosphere, the layer will have a thickness of more than a decimetre, and the effect of the air will then be peculiar. If the gas is of such a density that the glass envelope is beyond the range of this action, the gas beyond the limiting distance will be cold, but if the effect reach the glass, combustion will take place to it. There will then be a procession of warm molecules towards the glass, where they will be cooled down, and form a number of cold, slow-moving molecules, which will go back to the disc and beyond it. And these processions will be intermixed with molecular taking place in every part. In consequence of this, very few molecules will reach the front of the disc, and the number of such, however, will be carried forward in the right direction. Belong as these processions go on, the slowly moving molecules which reach the front of the disc are thrown off more vigorously than from the back. Prof. Stoney considers the pressure thus produced to be that measured by Mr. Crookes. With a pressure of the gas of twiglith of an atmosphere, the thickness of the layer of A C, will produce the force actually observed, while if the exhaustion be carried to twiglith the elevation of temperature necessary will be A' C. Those who the greater pressures with tens- pentures will suffice, but other influences will then be brought into play leading to an opposite direction. It was pointed out that on this theory the action may be considered as closely resembling electricity, and Mr. Crookes has shown that the glass envelope is often itself slightly electrified.

TELEGRAPHING BY THE AURORAL CURRENT.

MR. G. N. HEWOOD, telegraphic operator at London, Texas, 14th, 1874, his attention was attracted to a peculiar action in the record his relay magnet, similar to that found during a thirty. It gradually increased until the relay worked at some one was signaling and closing the circuit. At first he almost on the line, but was at a loss to account for the unusually disturbed condition of the current. This same atmospheric electrical disturbance was going on for two hours succeeded, and while using his imagination as to what that self to his mind. Then some disconnected the battery from the ing and closing of the keys, as if the battery had never been disconnected. He worked the line for nearly two hours without any apparent difficulty, without a single battery being in circuit ; but after the first two hours it became too weak to ing. As it grew weaker it permanently settled to zero. Upon try in opposition to the direction in which his battery formerly tery with reference to the line, so as to neutralize with the natural current, which was strong enough to demagnetize the the battery current when connected in opposition to it. turning every trace of it had disappeared.

Potculum Changed into Electricity and Light.

PROFESSOR W. A. ANTHONY, in discourse of a recent series of experiments with an electro-magnetic machine of his Gramme pattern, made the following interesting observations:

The electric machine was driven by a five horse Brayton petroleum air engine. The engine consumed a little over six and a half pounds of crude petroleum per hour.

The lamp used in the engine, by which the explosive mixture is fired, had a one inch coil wire, and consumed 29·8 grammes (420 grains) of oil per hour. The power resulting from the motion of the engine, when applied to the electric machine, produced a current of electricity, or electric light, by using an illuminating power equal to that of 241 of the lamps mentioned, showing that three times more light may be produced from a given quantity of oil, if its energy is converted first into mechanical power and then into electricity, than if the oil is directly burned in a lamp.—*Scientific American.*

JOURNAL OF THE TELEGRAPH.

VOL. VIII. NO. 17. NEW YORK, SEPTEMBER 1, 1875. WHOLE NO. 193.

THE PHENOMENA OF CHARGE AND DISCHARGE IN TELEGRAPHIC LINES.

If one connect one end of a telegraph line with one pole of a battery and place the other pole of the battery and the other end of the line in connection with the earth, the current pervades the entire line almost instantaneously, reaching the farther end at the line at nearly the same moment that contact is made with the battery. Upon the first appearance of the current at the extreme end of the line, however, it is exceedingly weak, but it constantly increases in strength until it reaches a maximum, which it maintains without further change so long as the connection with the battery continues, and the line is perfectly insulated. If we insert a galvanometer at the distant end of the line, the latter shows no deflection until the current becomes sufficiently strong to influence the needle. The more sensitive the galvanometer is, the sooner it will be affected by the current and the shorter will be the time that will elapse between the making of the contact with the battery and the perceptible appearance of the current at the distant end. The deflection of the needle continually increases as the strength of current augments, but does not become constant until the current has attained its maximum, which requires a perceptible though very brief interval of time. If we insert several galvanometers at different points upon a long line, and make connection with the battery, the needle of the galvanometer which is nearest the battery will first be deflected, a moment later the second follows, then the third, and finally the most distant from the battery. In the case of all the galvanometers that are on the hull of the line nearest the battery, the angles of deflection will be equal, and will remain so while the connection with the galvanometers that are placed on the second half of the line, if they are sensitive, also remain stable at first, continually increase until after a certain time has elapsed, when the galvanometers at the extreme points all show the same deflection, which continues permanently if the insulation of the line remains constant.

The condition of the line during the time that the strength of current is constantly increasing, that is, from the moment that the line is connected with the battery until the strength of current in all parts of the line is the same, is called the variable state, to distinguish it from the permanent state in which no changes of this kind occur. The permanent state occurs first in the middle of the line, and it continues there four times sooner than at either end.

The time which it takes the current to make itself manifest upon the galvanometer depends upon the sensitiveness of the latter, consequently, neither the instant when the first portion of the current reaches the end of the line, nor the moment when the current begins to be constant, can be exactly determined. Of two galvanometers, the one which is most sensitive is first to show the passage of a current. In consequence of this the duration of the variable condition cannot be stated with absolute exactness, and we are obliged to confine ourselves to the determination of the time which is required for the current to reach a state that approximates closely to the permanent state.

DURATION OF THE VARIABLE STATE.

If we assume with Ohm that electricity flows through a wire in accordance with the same laws that govern the diffusion of heat in a rod which is heated at one end, we are led to the conclusion that the duration of the variable state is in proportion to the square of the length of the line. If for instance a certain line is 2, 3, 4, or more times as long as an-

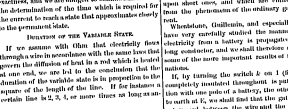

Figure 1.

other, then the duration of the variable state is 4, 9, 16, etc., times as long as it is for the shorter line.

Gangain and Guillemin have experimentally proved the accuracy of this law. The duration of the variable state depends also upon the conductivity, the sectional area and the degree of insulation of the line, and upon the quantity of electricity which is required to produce a certain potential through the unit length of the line. In an ordinary iron telegraph wire of No. 8 gauge the duration for a length of 300 miles, varies according to atmospheric

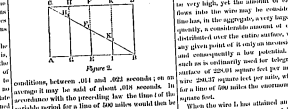

Figure 2.

conditions, between ·001 and ·022 seconds ; on an average it may be said of about ·008 seconds. In accordance with the preceding law, the time of the variable period for a line of 600 miles would then be given by the proportion

$$t_1 : .008 :: 1 : (2)^2$$

or

$$t_1 = .0080001022 \text{ second.}$$

We shall hereafter see what influence the other circumstances above mentioned have upon the duration of the variable period.

CHARGE OF AN INSULATED LONG LINE.

Ohm's laws give no sufficient explanation concerning the manner in which electricity diffuses itself under some conditions. Many phenomena appear upon long telegraph lines which we do not notice upon short ones, and which are entirely distinct from the phenomena of the ordinary galvanic current.

Wheatstone, Guillemin, and especially Gangain, have very carefully studied the manner in which electricity from a battery is propagated through a long conductor, and we shall therefore state briefly some of the more important results of these examinations.

If, by turning the switch *k* on 1 (fig. 1) a wire completely insulated throughout is put in connection with one pole of a battery, the other pole being to earth at E, we shall find that the galvanometer G, being perfectly insulated, at the moment the switch is turned on 1. This current, which is perceived in proportion to the length of the line, originates therefore without the existence of a closed circuit, but its intensity diminishes only for a very small portion of a second. After the first and almost instantaneous deflection, the needle of the galvanometer again returns to its state of rest, or at most only shows a very small deflection in consequence of the line not being perfectly insulated.

As soon as the line wire L is connected to the pole of the battery, it becomes electrified, and almost throughout its entire length this same potential as the pole of the battery itself possesses ; consequently, as the current passes into the wire it manifests it presence first in the neighborhood of the battery. This effect, however, ceases as soon as the charge reaches the extreme end of the line, and the line itself attains at all points the same potential as the battery pole. The earth E with which the other pole of the battery is connected, may be replaced by any other conductor having the same resistance as the line L.

Although the electrical potential of the battery and of the separate parts of the line may not be very high, yet the amount of electricity which these into the wire may be considerable, on a long line has, in the aggregate, a very large battery, consequently, a considerable amount of electricity will be obtained over the entire surface, would present at any given point of it only an inconsiderable density, and consequently a low potential. A line 3 wire, such as is ordinarily used for telegraph lines, has a surface of 226·01 square feet per mile, and a No. 6 surface of 280·01 square feet per mile, which would give for a line of 600 miles the enormous surface 110,155 square feet.

When the wire L has attained an equal potential at all points, in consequence of having been connected with the pole of the battery, the wire is said to be statically charged, and the operation is termed charging the wire.

The charge extends only over the surface of the wire, and its amount is determined both by the magnitude and form of this surface. It is proportional to the length of the line when the

well insulated that all its parts attain the same potential; it increases also with the volume of the conductor, and is in exact proportion to the electromotive force of the battery.

DISCHARGE OF INSULATED LEAD LINES.

If we insulate a charged conductor L (fig. 1) by removing the switch S from 1 and placing it between 1 and 2, thus breaking connection with the battery, its electrical condition will remain unaltered, provided the insulation is perfect. As this is never actually the case in practice, the charge of the line passes off at the points of support and at such other points as derivations may occur. The more defective the insulation is, the sooner will the charge become dissipated.

This flow of electricity from a charged wire takes place with extreming rapidity on air lines. Even with the best insulated ones it rarely occupies more than a very small fraction of a second. The case is quite different with underground or submarine lines, in which the wire is carefully covered with insulating substances. A tolerably well insulated cable will, according to circumstances, retain its charge so well that even after a lapse of twenty or thirty minutes it will only have lost half of the electricity which it received when being charged.

When, however, after having charged the wire L, we separate it from the battery, and then, before any considerable loss of electricity occurs, connect the same end of the wire to the earth E, the electricity which at first flowed in, suddenly flows out into the line again, and the inserted galvanometer G marks the passage of a momentary current whose direction is opposite to that of the charging current. This may be accomplished in the simplest way by quickly turning the switch S on 2, after having placed it on 1 to charge the wire. By this means the end a of the wire is separated from the battery and placed in connection with the earth. This second current flowing from the line to the earth is called the discharge or return current.

If, instead of the end a, we had connected the end b of the line to earth, then the discharge current would have taken place in the direction a b; and the deflection of the needle of a galvanometer inserted at b would have been in a direction opposite to that of the preceding one.

When the line is discharged, the galvanometer needle is also deflected to a certain maximum, and then after several oscillations, finally returns again to its state of rest. As the defective force of the return current acts on the needle in these cases almost instantaneously, the mode of its action upon the needle is similar to that of a blow against a pendulum, that is to say, the defective force, or the magnitude of the discharge, is in accordance with physical laws, proportional to the sine of half the angle of deflection, and is entirely independent of the kind of galvanometer used.

It is evident that the same law also holds good for the charge, consequently if we indicate the magnitude of the charge by A, that of the discharge by B, and the corresponding angles of deflection by α and β respectively, using the same galvanometer for both deflections, then,

$$A : B = \sin \frac{\alpha}{2} : \sin \frac{\beta}{2}$$

As the electricity with which the wire is charged becomes gradually dissipated after the charge has been effected, either through the air or by means of other partial conductors, the return current becomes proportionately weaker as a greater length of time elapses between the charging and discharging. If the line were perfectly insulated, and there was, however, no escape of the electricity, or if the discharge could be made to take place simultaneously with the interruption of the battery, the discharge current would be just as strong as the charge current; but as this can in reality never occur, and as some time always elapses between the operations, the discharge current is necessarily always less than the charge current.

The more perfectly a line is insulated the less will be the loss of the electricity with which it is charged, in a given time, consequently, the proportion between the quantity lost and the primitive charge will be found to serve as a means of determining the condition of the insulation.

If we retain the same indications for quantity of charge and discharge as before, and assume that the discharge takes place 1 second after the charge, then the line in this space of time loses a quantity of electricity A–B. The proportion between this loss, caused by imbibitions or leakage, or, in general, by defective insulation, and the primitive charge, amounts, therefore, for half a second, to A – B. The smaller this proportion, the better is the insulation of the line.

If, as of late of 5 to 10 miles in length these conjunts are not perceptible even when using a battery of 300 elements, but with a length of 20 miles both properties are easily rendered apparent by using a powerful battery and a very sensitive galvanometer; when the length exceeds 100 miles even the relay magnets of the telegraph apparatus will show them.

In what has been said it is to be borne in mind that the end b of the line (L fig. 1) is insulated, while the charging or discharging is done at the end a.

CHARGING AND DISCHARGING A LAND LINE CONSIDERED AS EARTH.

If we put the end b of a land line L (fig. 1) to earth by connecting b with A_1 and earth plate E_2 a constant current, as we know, traverses the line as soon as the battery is connected. This current is indicated by a permanent deflection of the galvanometer needle and lasts as long as the battery remains in circuit. In this case the electric potential of each point of the line is not equally great, but decreases continuously throughout from the pole 1 to the extreme end A_2 and E_2. Owing to this decrease of potential from point to point, a constant flow of electricity from the battery through the line to the earth is thus charged with electricity, but the amount of the charge is smaller than when the end b is insulated, and the time in the latter case the potential is the same at all points.

Hlatter very properly compares both the charging and discharging of a line, when the distant end is insulated and uninsulated, with the movement of a gas through a tube, one of the ends of which communicates with a very large reservoir, in which the gas is under a constant pressure, the other end being placed in a vacuum.

If we interrupt the connection with the vacuum and close the opening of the tube at this end, the gas does into the tube only so long as the pressure is not the same at all points.

This is precisely the case with a telegraph line when uninsulated. The reservoir represents the battery, the tube the wire, and the gas the electricity.*

* The comparison, however, is not exact, since in charging the wire with electricity we need not suppose a real propagation of the electrical fluid from one point to another, but we should rather consider it to be the result of a progressive decomposition and recomposition of the natural electricity.

When, on the contrary, the end of the line is placed in the vacuum, and the gas is allowed to flow through it, then the pressure in the immediate neighborhood of the reservoir is equal to the pressure of the gas in the reservoir itself, and it decreases gradually to the end of the tube where it becomes zero. Consequently the total amount of gas in such a tube is less than in the former case, when the tube is closed at the end.

We may obtain a good idea of the condition of the static charge in a line insulated at the remote end, and of one having the remote end connected to earth, if we suppose the electric potential of the separate points to be represented by vertical lines which are erected at the respective points.

Let A B (fig. 2) be the length of the line; suppose it to be connected to one pole of the battery of A, and let the potential at this pole be represent by the vertical line AC erected at A B. If the extreme end B of the line is now insulated, by which the potential at all points of the line becomes equal to AC, then the vertical lines C H, F F, I K, B B, which are each equal to AC, represent the potential at the points A, G, E, I, B. The total charge of the line is, therefore, the sum of all the perpendicularies of the length A C, which it is possible to conceive of as existing between A and B; that is to say, it is proportional to the contents of the rectangle A C B R.

When, on the contrary, the end B is connected to earth, then the electric potential from A towards B decreases in proportion to the distances taken, if we still represent it at A by A C, then for the distances A G = $\frac{1}{4}$ A B, A E = $\frac{1}{2}$ A B, A I = $\frac{3}{4}$ A B, it will be respectively $\frac{3}{4}$ A C, $\frac{1}{2}$ A C, and at the point B it falls to zero. Consequently, if we draw the line C B, the verticals G H, E F, I K, will represent the charges corresponding to the points G, E, I. The total charge of the line A B is, therefore, equal to the sum of all the verticals included between A B and C B. Consequently, it is proportional to the area of the triangle A C B.

It follows, then, that the total charge of a line when distant and is connected to earth, is only half as great as when the line is completely insulated.

RETURN CURRENT IN LAND LINES WHEN PUT TO EARTH.

When the line L (fig. 1) is in contact with earth at E_2 at the point b, and the switch S is turned on 1, then L receives a charge half as great as if it were insulated. If now the connection between the line and battery is broken, the electricity which is distributed on the line rapidly escapes through b to the earth E_2. For this reason, the duration of the discharge for ordinary land lines is exceedingly short, or any rate, very much shorter than when the line is insulated at A; in which case the discharge can only be effected through the air and by the poles, as long it remains between 1 and 2.

When, however, the line is very long, for instance 100 miles or more, the discharge does not take place in an immeasurably short period of time.

If we turn the switch very quickly from its position 1 to 2, then the discharge takes place in two opposite directions; the greater part of the charge in the vicinity of the battery passes over A and b to earth E_2 producing the return current, whose direction is opposite to the direction of the charge; the other and smaller part flows in the direction of the charge (from a to b), through b to earth E_2. The return current may be observed on a sensitive galvanometer G.

The discharge may also be delayed and made apparent on a line without insulating its end b, by inserting a considerable resistance between b and the earth E_2.

As this supposes to a considerable extent the flow of electricity at A, the return current at a will be much stronger when the switch S is quickly turned from 1 to 2.

The same effect takes place when, instead on an artificial resistance at b, a considerable resistance is accidentally present in the line itself, such for instances as may occur in consequence of defective wire connections or bad connections in the instruments. This fact often enables us to form a conclusion from the appearance of the return current, whether there is a defect at the other end of the line.

We must not however, confound the return current with the so-called extra current, which originates at the moment the battery is placed in circuit, and also opposes the main current, this extra current occurs only at the moment that the battery is closed while the extra current which appears at the interruption of the battery, has the same direction as the main current in the line.

On breaking battery connection by turning the switch S (fig. 1), from 1 to 2 quickly, there results, especially in very dry weather and upon long lines, say of at least 250 miles in length, an extra current as well as a return current. These are, however, of opposite direction; the return current being opposite to that of the battery current, the extra current opposite, that is in the same direction as the battery current. By means of a very sensitive galvanometer we may therefore see which of the two is the strongest.

On very short lines the extra current which appears when the battery is interrupted and whose direction is the same as the line current, is the most powerful, that is to say, the extra current is more powerful the shorter the line is, while the return current may not be perceptible at all.

If the length of the line is increased and the battery suddenly disconnected, by turning the switch S from 1 to 2, the return current makes its appearance, and is distinguished from the extra current by its direction. It increases also, in the same proportion that the length of the line is increased.

Both currents may be recognized when the battery is suddenly interrupted and the line connected to the ground, with the ordinary Morse duplex apparatus, by the attraction of the armature levers. With the step-by-step printing instruments both currents are increased when the line is more than 100 miles long and the transmitter makes from 10 to 12 pulsations per second.

Electrical Phenomenon

LAST night I noticed a powerful development of electricity in a curious manner. I had thrown a piece of white cloth, whitened paper upon a hot fire which was tolerably full of ashes. When it was charred so as to be black and brittle, I happened to take it up with my fingers. The intense heat of the ashes caused me to drop the piece of paper, which, on striking the floor, was broken into a number of small pieces, each was capable of rotating (though with very great friction). When brought into contact with other supplies of paper forcibly, I experimented with these pieces for several minutes without perceiving any diminution in their electrification. Both sides of the paper seemed to be in the same condition. I then laid them down, and left the room to finish a piece of writing—a test of the nature of the electricity. But by the time I returned, all trace of electricity was gone, and by no means could I repeat the experiment so as to get the slightest charge of electricity.

It is more than probable that the electricity was developed by the chemical action of combustion of the coals, and that the dry air rising up and heating just the paper acted as a carrier of electricity of one kind to the paper, and of the opposite kind from it, until it acquired a very high potential. I should be interesting to learn exactly in what manner induction takes place, and whether the electrification was positive or negative.

Ardenconlee College, Glasgow GEORGE FORBES

The results of a series of experiments by M. Cazin and the heat measurements gave the following laws: "When straight iron cores is surrounded by a series of similar coils, when the current flows in alternately opposite directions, and when these coils produce poles at equal distances from each other, the maximum heat which are produced in the core by the same intermittent current are inversely proportional to the squares of the number of the coils."

In the foregoing experiments heat was developed in the core, while a regularly interrupted current produced in this core a series of magnetizations and demagnetizations. M. Cazin now sought to determine the amount of the developed of heat, and proceeded as follows: Round the iron core in the percolaux thermometer two coils of 630 turns were passed, one of them being in the interrupted magnetizing circuit, while the other formed a special circuit, while in each turn of the interrupting apparatus was closed. The first coil could now induce a current in the second, if the closures of the two circuits took place at the proper times, as might be arranged at will. These experiments gave the greatest development of heat when the circuit of the second spiral remained continually open. The heat was not altered when the circuit was closed at closing of the magnetizing current. There is thus no thermal action during the variable period of closure. Lastly, the heat was smaller when the circuit of the second spiral, during the opening of the inducing circuit, was closed; it was then as much as the half. It thus proved that the production of the magnetic heat takes place during the opening of the voltaic circuit, consequently, that it accompanies the disappearance of magnetism in the core.

Absorption of free hydrogen under the influence of the electric current.

The electric current—g–ll, Berthelot—hydrogen is absorbed by organic matter under the influence of the electric current much more rapidly than ozonization, and with the formation of a polymer of C_4H_{10}, or $(C_4H_{10})_n$. Similar absorption occurs in the case of terebenthine and amylene.

The Chemical News.

No. 857.

On electrical phenomena, the alleged etheric force, and experiments as to its identity with ordinary electricity.—E. J. Houston and E. Thomson.—The results described as manifestations classed as "etheric" can depend solely to inverse currents of induced electricity.

[2911.]—Spontaneous of Telegraph Wire.—The use to only our wires with insulators, at least some faults, and prevent the simultaneous being carried to your board. The pieces of wood are best steeped in paraffine, which will not prevent the sound being carried to your board. Paraffine is a much better conductor of electricity than wood. Leaving the upper ends of the wires as possible—feet, you must remember that the conductivity of the wire used will be increased by the conductivity of the wire used will be increased with; hence whatever you use will be increased by the conductivity of the wire. Between the insulator and the wall I would place a piece of thick, soft, and dry woollen fabric, well wound round the wire, and then well packed before entering the wall. The insulator, so as to make a cushion on which the wire would rest. Before the insulator, I would have wooden cleats attached loosely to the wire to prevent them using the wire of 1, 2, 3, and 7 inches of distance from one another. The object of these cleats is to prevent the wires coming into contact. The shape of a V shape, with two holes running through from side to side, and the wire to be passed through them, will never be ascertained. Paper, or that kind of paper, lace and tin, dry on each side. These pieces of lace would vibrate independently of the wire, and would destroy the vibrations of the wire to a considerable extent, especially if placed at the extremities. I have seen the wire fastened to the inside of the V still greater, and by means of a wooden wedge. This will further reduce the vibrations of the wire. Of course, you will run the V pieces into each other, and will run them the V pieces into each other, and will run them the V pieces into each other, and will run them

ELECTRO-CAPILLARY PHENOMENA.

The electro-capillary machine of Lippmann and his capillary electrometer, besides the capillary electroscope of Wagner Hermann and the electro-chemical relay of Wiedemann, are all illustrations of a phenomenon resulting from *application* of an electric current. I am not aware that the *converse* phenomenon is so generally known, namely, that the motion of a conductor in the tube *produces* an electric current. If we substitute a galvanometer for the battery in a Lippmann capillary electrometer, and move the liver by hand, the galvanometer needle is deflected. Similarly, if in any of the electro-capillary arrangements a galvanometer is substituted for the battery and a bubble caused to move by mechanical action, electrical currents are produced which deflect the galvanometer needle.

The following small instrument may serve to show this action for lecture purposes: *e e* is a glass tube of any convenient bore, say 10 to 30 millimetres, by

300 mm. length; *k* is a cork fitting tightly into the middle of the tube, and perforated in two places where are inserted—at *c* a tube of 1 mm. bore, slightly longer than the cork is thick, and at *d* a longer tube, extending half way into both compartments. The ends of the tube *e* are stopped by the corks *e e*, through which pass the platinum wires *f g*. Sufficient mercury to quarter fill each compartment is introduced into the tube *e e*, with a small quantity of dilute sulphuric acid. The apparatus being now complete, the wires *f* and *g* are connected to the terminals of a somewhat delicate galvanometer.

By inverting the tube, as is done with an hour or egg glass, a current flows through the galvanometer from the upper mercury mass through the tube *c* into the tube *d* in air bubbles, thence traversing the lower mass, and finally in an opposite direction, the wires being at first completely sealed. To this the short pieces of tube and hermetically sealed platinum wires are to be fitted and fitted with a commutator, so as to be made to give a constant current in one direction, and in the opposite direction.

With a fine funnel, the tube of which is drawn out to a fine point placed above *c*, a very small quantity of mercury and dilute acid were made to flow into the funnel and lower vessel to the galvanometer, some interesting results are to be noticed which serve to throw considerable light on the action in electro-capillary phenomena. It will be found that when the mercury breaks away from the funnel a very great height interrupted, and of course no current passes through the galvanometer; and when the funnel is brought so as to dip into the lower vessel as in the figure, only a continuous column, there is an short circuit and the galvanometer needle undeflected. There is a point, constantly changing, between these two positions giving a maximum current in the outer circuit, and this is easily found experimentally.—P. HIGGS.—*Nature*.

Curious Electrical Experiment.

If an ebonite electrophorus be whipped with a fox tail, it is negatively excited, and the condenser gives positive sparks. If, again, the electrophorus be rubbed with leather on which is some musicle gold, the ebonite disk is positively excited, and the condenser gives negative sparks. It is stated by M. Schlosser, however, (*Journalof's Annales*), that if the surface ebonite disk be excited on one side with the fox-tail, on the *other side* with musicle gold on leather, one may at any moment obtain from the same disk positive or negative electricity, according as the one or the other surface of the electrophorus is used as the source. The most important point in this double excitation is the very much greater length of spark, as is readily observed by the eye. On the other hand, considerably shorter sparks are obtained from the same electrophorus when both sides are similarly excited, for example, whipped with the fox tail.

Diagnosis by Telegraph.—We clip the following from an Eastern paper: "Recording pulse beats by telegraph is a feat recently accomplished by Dr. Upham, who, in a lecture lately delivered in Salem, Mass., by telegraphic communication with the Boston City Hospital, exhibited the phenomena in question by throwing a beam of light upon the wall of the lecture room, which vibrated in unison with the exciting cause."

This reminds us of the pleasure we enjoyed when at the anniversary of Science, at Salem, Mass., in 1874, the Boston City Hospital were made audible to those in Salem by telegraph by telegraphic communication with the Boston City Hospital, exhibited the phenomena in question by throwing a beam of light upon the wall of the lecture room, which vibrated in unison with the exciting cause."

This reminds us of the pleasure we enjoyed when at the anniversary of Science, at Salem, Mass., in 1874, the Boston City Hospital were made audible to those in Salem by telegraph by telegraphic communication with the Boston City Hospital, different beats of the pulse of various patients in the pulse in patients laboring under attacks of pneumonia, phthisis, fever and ague, etc., was quite marked, and perfectly satisfactory to give data by which to recognize the disease. Making the vibrations also visible is a step in advance.

Something New in Electricity.—If an ebonite electrophorus be whipped with a fox-tail, it is negatively excited, and the condenser gives positive sparks. If, again, the electrophorus be rubbed with leather on which is some musicle gold, the ebonite disk is positively excited, and the condenser gives negative sparks. It is stated by M. Schlosser, however, (*Journalof's Annales*), that if the surface ebonite disk be excited on one side with the fox-tail, on the other with musicle gold on leather, one may at any moment obtain from the same disk positive or negative electricity, according as the one or the other surface of the electrophorus is used as the source. The most important point in this double excitation is the very much greater *length of spark*, as is readily observed by the eye. On the other hand, considerably shorter sparks are obtained from the same electrophorus when both sides are similarly excited, for example, whipped with the fox-tail.

ELECTRICAL SMOKE FIGURES.

When frictional electricity is caused to act on quiet smoke surfaces, it produces (according to Prof. Antolik, who has recently made observations on the subject) a number of very curious and pretty phenomena.

To produce the smoke surfaces tobacco was used, mixed with a little sugar, and the mixture burnt in an iron pipe surrounded with cold water. By means of a bellows, with caoutchouc tube, the burning was slowly maintained; the smoke was conducted through a caoutchouc tube to a second cooling apparatus, thence through a glass tube and paper funnel, finally streaming out on a smooth black table, and expanding in a circular surface. If the smoke be not properly cooled it forms irregular waves on the table, which are unsuitable for the experiment.

If, now, a Leyden jar, with about 500 sq. cms., internal coating, and charged with positive electricity, be brought to about one metre above the smoke surface, there appear in the whole of the latter for a moment, proceeding outwards from a central point of action, sharply defined cloudlets of roundish and elliptical form. The entire smoke-surface divides into numerous concentric surfaces, which appear to be as numerously broken, though only in a regular way. This is the climax of the experiment, but it lasts only a brief to one second. Almost at the same moment has the aspect of the well-known bands' wood clouds. In the most favorable moments these appear, but they immediately vanish. The number of cloudlets may in some cases be estimated as several thousands; their size varies from 1 to 2 sq. cms. or more.

A part of the above-named boundaries of an individual cloudlet less remain still visible some time, and expand from the middle point towards the outer edges of the smoke surface.

The production of the figures appears to M. Antolik to be due to a communication of electricity, and not to be an effect of induction, for on using instead of a thin glass disc an ebonite disc even the smoke surface, the figures were formed only round about the glass disc, not under it. Perhaps," he says, "the formation of the phenomenon may be ascribed to very slight and long continued electric oscillations, or to a series of extremely short rises from the Leyden jar to the smoke surface, and causing in the cloudlets themselves a momentary separation of electricity. In this way the phenomena may be explained, yet its cause is not yet given with certainty. The production of the concentric circles may be attributed to the smoke waves arising in the streaming out from the paper funnel, the coherence of which waves seems to persist, though at a short distance from the funnel they flow into each other. The individual smoke-waves separate from each other, and in this state go further if the charged jar be continually brought nearer to the funnel. The initial cloudlets (more difficult to explain than the concentric circles) have probably their source in the regular arrangement of the cloudlets, which flow into each other pretty."

The figures may be maintained even if the jar be neared to the smoke-surface slowly, but they are always more and more blended.

A second phenomenon is that, if the somewhat weakened jar be brought near the smoke-surface, the cloudlets at a certain limit assume, instead of the roundish and elliptic forms, a ruffled (*gekrauselter*) appearance (like tan-maker's wool). Individual cloudlets rise, whirling slowly, but mostly fall back again. The ruffled appearance is only of some time, especially if they occur near the edge of the smoke, where at the same time traces of the radial divisions are perceptible. M. Antolik considers them a result of the individual rays.

If, now, the jar be brought quite close to the smoke layer, so that a small spark between it and it take place, the entire smoke layer is quickly driven outwards in form of a concentric circular surface. But, before this stage, the smoke commonly disappears on the table, while the small surface particles in it adhere to the table, and cannot now free themselves from it.

A third phenomenon, when it once occurs, subsists till the last moment of the experiment. There appear, namely, on the smoke layer, winding and sharply defined furrows, which seem round, similar-like, in the layer, and follow the movements of the Leyden jar. At first there are only a few furrows, often only one; but they afterwards multiply greatly.

This phenomenon seems to point to the fact that on the head of the furrow jar are small particles of dust from which, as from points, the electric wind streams out in infinite fine cone-like bundles, which seem to very strands and uncommonly delicate at their surface, since the borders of the furrows they produce seem to be sharply cut. A furrow often sinks only to the half of the by no means thick smoke layer, and in it the cloudlets of the first phenomenon occur and fill it up. If we hold the jar quite still on production of the furrows, there appear only sharp larger and smaller points in the smoke surface, which continuously maintain their positions, even when the smoke waves stream more quickly out of the paper funnel. If the jar be moved, however, and only two or three cone-like rays occur over each other, they wind parallel to each other. The outlines of the furrows remain visible several seconds, especially at the border of the smoke surface, where this is less movable. Once they occur, they are broader the farther the jar is from the smoke surface.

Good conductors and glass tables under the smoke layer seem to have no influence on all these phenomena. If the Leyden jar be charged with negative electricity the same phenomenon occur, only the jar must be brought much nearer to the smoke.

If these phenomenon seem to render it probable that the hazily-broad clouds visible in the sky have their cause in the air currents saturated with electricity. Whether these are positively or negatively electrified they must certainly act on the cooled water vapor of the atmosphere, even at a great height, either commensalitively or inductively. The needed air must highly favor the action at a distance of the electricity, and accordingly the clouds in question may continue at rest a long time in the place of their origination.

The Northern Lights.

The Finland observations of northern lights in the years 1846-1877, numbering 1,160, have recently been compared by M. Peitz, in the *Wochenschrift für Astronomie*, with auror.i phenomena of the same period in all other regions. This comparison leads to results which are interesting as bearing on the theory of the phenomenon. The table shows that of 2,025 days of the months August to April, on which northern lights were seen, 1,167 days were days of northern light for Finland. On 784 days northern lights were visible simultaneously in America, and mostly also in Europe; on 101 days only in Europe, and on 282 days only in Finland. They were on 88 days visible in Europe and America, and not visible in Finland. The conclusion is thus reached that a large portion of the polar lights have as very great extension, or that the causes producing them more often be of a very local nature, while in another portion of the phenomenon the regions of simultaneous appearance are very considerable. The number of these phenomena which are limited to Finland is very small. With the increase of frequency of the phenomena, at the time of maximum, their number observed in Finland and America on the same day increases; while those observed in Finland and only in Europe, or those in Finland only, decrease. These relations correspond to the known law, that with the frequency the intensity and extent of the polar lights also increase.

Electric Fire Balls.

M. Planté reads in the foregoing experiments of his an explanation of the *feuâtre globulaire* or "fire ball." They show that with a sufficient quantity and tension of electricity we can obtain the electric light in a globular form. He therefore thinks that this manifestation of the lightning discharge is due to an abundant flow of electricity in the dynamic state in which great quantity and potential are united. These particular cases wherein the fire ball is seen to move and to stop are explained by the motion or rest of a column of humid air, strongly electrified and invisible, which serves for an electrode. In order to imitate this effect it suffices to oscillate the platinum electrode in the above experiments, pendulum fashion, over the water, or a metallic surface, when a little fire ball is seen to move over the surface opposed. This explanation of the fire ball has been advanced before by Mr. Cromwell F. Varley.

IS THE BODY AN ELECTRIC MACHINE?

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Allow me to bring the following (to me) strange phenomenon under the notice of your scientific readers. To many of them doubtless it will not be *strange*, and they will be able to account for it.

I have frequently observed during the past winter, on removing my innermost garment (a flannel vest), that the under surface has been *highly luminous*.

Sometimes the light is of a pale phosphorescent hue, like winter or sheet lightning; but often it assumes an angry red, like the forked dose, and at this latter case, when the house has been quite silent, I have distinctly heard that crackling sound characterized with the electric spark.

Is it possible that one bodier resemble so many Leyden jars fully charged? and that the flannel acts like the silk "robber" in producing electricity by friction on the person? and all this without any aid from Fahrenheiter's apparatus.

Let me add that I have noticed the above phenomenon only on *deep, frosty nights*, and that on undressing I have *hastily* taken off the fiery vest and thrown it *briskly* to some three or four feet distance.

I shall leave it to some of your learned readers to account for this. I can only assure them I was not mistaken, as I have often and closely observed it.

I hull with pleasure the appearance of your excellent paper, *The Electrician*.

Hoping some correspondent will enlighten me on the foregoing,

I am, sir, your obedient servant,

W. S. O. B.

CHEMICAL PHENOMENA PRODUCED BY ELECTRICITY.

By M. Berthelot.

Ozone is formed equally under the influence of both electricities, the oxygen in each tube only being in contact with the internal armature. The proportions are very variable; but as a rule the positive electricity produces in the majority of cases the more ozone. In none of the experiments made with the Holtz machine was the *ozone* observed in smaller trace of nitrous compounds produced from mixtures of oxygen and nitrogen. Another point of fact. With the effects of Rühmkorff's apparatus traces have been observed, but only at the highest tension. Anything, on the other hand, is produced in notable quantity, in the cases of ozonic compounds included along with platinum in tubes overcoming a metallic armature, independent of the discharges of the Holtz machine. The absorption of oxygen by organic compounds is effected equally by both electricities, and at the weakest as well as at the greatest tensions. I thought the final results in the former case to be larger. Along with the nitrogenous compounds there is formed and a trace of ammonia, nitric or nitrous acid, or hydrocyanic acid.

Influence of Electricity upon Evaporation.—M. Mascart.—The author has examined if the slow formation of vapours is modified by the influence of electrized bodies. A number of small evaporating capsules, communicating with the ground, and containing, some water and others moist earth, were placed beneath conductors kept in a constant electric state. The results of evaporation was always increased beneath the conductors, whether the electricity was + or −, sometimes being even doubled.

ELECTRICAL MOVEMENTS OF CAMPHOR ON WATER.*

By P. Casamajor.

You are doubtless familiar with the singular motions of camphor when placed on the surface of water, which are of such extraordinary nature as to attract the attention of even the most careless observer. Very eminent philosophers have studied these wonderful gyrations, but little has resulted from their labors to explain the cause of this phenomenon. Among those who have worked on the subject we find the great Volta; we also find Venturi, Brugnatelli, Peverary, Biot, Matteucci, Marianini, Mr. Charles Tomlinson, who has given great attention to the subject, published in 1846 a work which has given a full account of previous labors of eminent physicists and chemists on these motions of camphor, to which he added many interesting experiments of his own. I cannot do better than advise those who wish to study carefully the history of the subject to consult this excellent book.

I find in this work that in 1788 Ibañez communicated to the Royal Society of Montpellier his observations on camphor, in which he advanced the idea that electricity is the cause of these singular motions. Ibañez states that camphor does not rotate on the surface of water placed in vessels of iron or copper, but the experiment succeeds very well in those made of glass, resin, or resin. He also states that while camphor is spinning in these vessels it is arrested if the surface is touched with the finger, with iron or brass wire, or a rod of wood, but glass, sealing-wax, or sulphur cannot arrest these motions.

This idea that the motions of camphor on water are due to electricity has met with the disapprobation of all subsequent observers, among whom may be found the names of men who are famous in the history of electricity. Coulomb among these is Alessandro Volta, who made several experiments to show that electricity had nothing to do with these motions.

Now, I propose to show you this evening that there is at certain moments between electricity and these motions of camphor, and, as Volta and other eminent philosophers of mine, in asserting that there is no such connection, I may be allowed to say that in the experimental sciences there is no authority of as much value as a fact, if the fact has been well observed. I propose, therefore, to show you the facts, and you are to be the observers. These facts naturally lead to the conclusion that the remarkable motions presented by camphor on the surface of water are electrical phenomena. I am not prepared at present to go beyond these facts, and drawing from them what seems inevitable conclusion. The phenomena which accompany these motions of camphor are very complex, and they have stubbornly resisted every attempt on my part to bring them under a general theory. I am in hope, however, that what I have to present this evening may serve to elucidate this interesting subject.

Camphor is not the only substance which moves spontaneously on the surface of water. Volta discovered the same property in benzoic and succinic acids. Others have added the stearoptenes of essential oils, the butyrates of soda and potash, carbolic acid, and citric acid; even pieces of cork soaked in ether will exhibit the same phenomenon for a short time. Naphthalen is mentioned in some books as possessing the same property, but I have found that it has not. These substances, with the exception of the stearoptenes, are heavier than water, and they are with difficulty kept afloat; they are also more soluble than is quite convenient for the experimenter. As they behave exactly in the same manner as camphor towards electricity, I will confine my remarks to camphor, as I have almost entirely confined my experiments to that substance.

If we throw pieces of camphor in water they rise to the surface, and, if the conditions are favorable, they will move on the water as if gifted with life. The larger fragments have slower motions than the smaller, which are due to their greater inertia, for if we subdivide the smallest the water with trepidation, after the ingenious idea of Mr. Tomlinson, we will find that the fragments that set from the larger pieces are stronger than from the smaller. The mobility of the latter being greater than that of the larger pieces the latter move away from the camphor. The shapes of the fragments of camphor have a great influence on the rapidity of their motions. A spherical piece will exhibit very little motion, while an elongated piece of the same volume, terminated by two pointed pyramids, will rotate with the greatest energy.

Very often the conditions under which the motions take place do not exist, and then camphor remains perfectly quiet on the surface of the water. It has generally been supposed that this arrested the surface of the water was covered with a film of dirt—either oil, dust, or something else—which for the time prevented the camphor from displaying itself. If, however, we keep the same water in a glass for several days, and place in it at different times fragments of the most pieces of camphor, we will sometimes have motions, and at other times none, which points to the conclusion that these irregularities are independent of the camphor, of the cleanliness of the water surface, and of the vessel which holds the water.

In the daytime the motions are more apt to take place than after sundown. Also when the weather is bright, or when it storms, than when the sky is cloudy and the air damp, but without any pressure of a storm. In many books we find that these motions of camphor on water are due to electricity. Although these may be truthful remarks I think this explanation is not satisfactory. When I began these researches I tried several times to determine these motions by heating the water, but without success; while at other times they appeared to me to be active on the surface of ice-water. Evaporation was clearly not the cause.

At this stage of the matter a gentleman, who is one of our associates, communicated to me an observation, which I here present to the meeting. Pieces of the same pieces of camphor are placed on several successive days in the same basin of water, sometimes there is motion and sometimes not. It was suggested at the same time that perhaps magnetism or terrestrial magnetism had to do with it.

Although magnetism as improbable, and not being aware at the time of the disapprobation by eminent philosophers of the existence of any connection between the motions of camphor and electricity, I made the following experiments, which I propose to repeat before you after reading this paper.

Having before me a beaker-glass holding water, on the surface of which small fragments of camphor were dancing with great energy, I rubbed a clean glass rod with flannel, and dipped the rod in the water, when I was surprised to see all the small pieces of camphor suddenly reduced to immobility. This experiment was repeated several times with fresh portions of water and of camphor, and always with the same result. Subsequently, the same glass rod, rubbed with tin-foil to render it electrically neutral, failed to produce any effect.

* Read before the American Chemical Society, October 4, 1877.

of my pleasure when the fragments of camphor began again their gyrations as the vulcanite insulated the water. I afterwards ascertained that a rod of shellac or of sulphur had the same effect as one of vulcanite.

The first deduction I made from this was that positive electricity stops these motions of camphor, while negative electricity increases their intensity. The deduction is however, was erroneous, as I subsequently found that if, after the motions are stopped by an excited glass rod, it is taken out, wiped dry, and excited again, and dipped in the water, and if the same operation is repeatedly gone over, the motions recommence and increase in intensity every time the excited glass rod is placed in the water. I also found that motions due to positive electricity may in their turn be stopped by dipping in the water an excited rod of vulcanite.

This requires a word of caution, as by rubbing glass very little positive electricity is obtained, when compared to the negative electricity which may be had, in the same manner and in the same glass, from vulcanite, shellac, or sulphur. This difference should be a negatively electrified rod be used with great nicety, as otherwise we bring in contact with the water more negative fluid than is necessary to neutralize the positive electricity, and, as a consequence, the water becomes at once negatively electrified, and the motions of camphor continue without interruption.

When the passage from one kind of electricity to another is very gradual there always occurs an intermediate stage at which, if several pieces of camphor are on the water, they become calm. Afterwards, when the water becomes more decidedly electric, these pieces just compassy, sometimes in quite a violent manner. A point of great importance to note is that when the surface of the water is electrically neutral, and pieces of camphor adhere to one another, they remain for a long time without perceptibly diminishing, while when they are in active motion they waste away in a much shorter time.

Gentlemen, I do not feel that I am against any rule of the strictest logic when I conclude from the facts which I have now presented that there is a connection between electricity and these motions of camphor. As to the cause of these motions, it resides in the camphor itself, and the explanation of the phenomenon must be found in some property possessed by certain substances of which camphor is the type, by virtue of which water which has been electrified dissolves them with greater rapidity than when not electrified. If a piece of camphor is held first on the surface of the water, and hydrosulphuric is sprinkled on its surface, as was done by Mr. Tomlinson, we will see currents flowing outwardly from the camphor. This may be explained by supposing that the water, holding camphor in solution by the aid of electricity as the camphor itself. If the fragments of camphor in small and are free, their great mobility allows them in their turn to be repulsed by the surface of the water, which makes comparatively stationary. Where we hold fast on the surface of the water a piece of camphor with an irregular surface, and sprinkle upon it the means of hydrosulphuric, the currents flowing outwardly from the camphor are very uneven in different directions. The inequality of the currents must, when the camphor is set free, determine its motion in a direction opposite to the resultant of these currents.

The enquiry which now presents itself relates to the nature of the remarkable property which enables some organic solids—such as camphor, benzoic acid, and others which I have not mentioned—to move on the surface of water when it is electrified. Duprectet ascribed these motions to a new force, which he called *repulsive force*. This amounted to giving up the problem. For my part, although I have endeavored to discover the nature of this property, the results which I have obtained are as yet too meagre and too contradictory for presentation before this Society. I do not despair, however, at some future day to present you with results worthy of your attention.

39

CRYSTALLINE SELENIUM.—Mr. R. Sabine, in the June number of the *Phil. Mag.*, fully describes a series of electrical experiments with crystalline selenium. After describing the methods he employed for inserting the platinum wires, he points out that it is necessary to discriminate between the resistance of the selenium and the resistance of the junctions. The resistance of the junctions was found to be very various, but did not depend upon the manner in which the wires were imbedded in the selenium. The conducting power of the selenium was found to differ materially in different parts of the same plate, and the resistances of junctions and selenium were both affected by variations of temperature in nearly an

equal ratio. Mr. Sabine experimented on the change of current strength when the current was reversed, but the majority of specimens did not alter sufficiently to afford definite evidence; and those recently prepared specimens which showed a considerable change generally gave unsteady readings. Careful investigation seems to point to the junctions, and not to the selenium, as the seat of this change. Professor W. G. Adams has pointed out that on increasing the battery power the apparent resistance of the selenium is diminished. Mr. Sabine states that, while the current was weak in some specimens, up to a certain limit, the resistance *increased* in one direction and *decreased* in the other direction, but after passing the limit in question the resistance decreased in both directions for any further increase of current, and suggests this result to be either a consequence of the operation of a Peltier effect or of electrolytic polarisation. He continues: "When the current passes through the selenium, it encounters a compound conductor analogous to that in which Peltier observed the cooling and heating effects of the junctions between antimony and bismuth. The crystals round the point of contact which cools contract, and have a tendency therefore to recede and to make the contact with their neighbours still worse; the crystals about the heated contact expand and improve the conduction. The effects are opposite, but not necessarily equal, because one junction may be more susceptible than the other. It is, of course, questionable how far this heating and cooling of an uncertain number of points of bad contact between the crystals of a selenium plate near the electrods would be sufficient to produce a sensible effect. But it is necessary to bear in mind the nature of the doubtful contacts which we are presented with, and which the smallest conceivable approach or recession may improve immensely or break entirely. The supposition that the behaviour is due to polarisation is the more probable. The increase of the resistance with increasing current (when weak) in one direction indicates the existence in the selenium of a small independent electromotive force, and leads to the suspicion that a portion of the material in contact with one of the platinum electrodes is in an electrolytic condition, or both perhaps, one being more so than the other. As the measuring current increases in strength, it appears to polarise the electrodes in the selenium, as in an ordinary electrolytic conductor, and the small independent current is overpowered and lost sight of. The apparent decrement of resistance by increasing the battery is probably due to the fact that the polarisation increases in a less ratio than the measuring current, so that when this current is weak the polarisation is proportionally stronger, and the apparent resistance higher than when the measuring current is strong. The discharge after removing the battery is such as would answer to the depolarisation of an electrolyte. The experiments of Mr. Sabine on the action of light on selenium lead him to conclude that it is a surface action. He made up a plate in the form of a galvanic element, so that the surface alone might come under experiment. A platinum wire was fused into it by which it was suspended in a test-tube. The back of the plate and the wire near it were insulated with a coat of varnish. The apparatus was placed in a lighttight box, in which a shutter could be open to admit light on the uncovered face. Platinum foil was the opposing surface, and in the dark the E.M.F. of the element was 0·112 volt., the selenium being positive to the platinum. On admitting diffused day-light the selenium became negative to the Pt., with an E.M.F of 0·66 volt. The paper also shows that the action of heat is identical with that of light.

EFFECT OF FLAME ON AN ELECTRIC SPARK.—Have any recent experiments been made in this direction? We know, for example, that M. Mische inserted a jet from a glass tube drawn out to a point, with a flame an inch long and one-eighth of an inch in diameter, between the terminals of a Holtz machine, and increased by this means the length of the spark from ten inches to more than twelve. J. A. F.

Nitric Acid Produced by the Electric Light.

MR. T. WILLS, F.C.S., has been making some experiments on the production of oxides of nitrogen in the electric arc. The atmosphere of course consists mainly of oxygen and nitrogen, but simply in a state of mechanical mixture; if those gases become chemically combined, they form several oxides of nitrogen, most of which are strong and corrosive acids. At a high temperature small quantities of these gases can be made to unite. This is the case when electric sparks are passed through air; and during the combustion in air of a very hot flame, such as that of hydrogen; it therefore seemed probable that, as the temperature of the electric arc is undoubtedly very high, nitric acid, or some other oxide of nitrogen, might be produced by the electric light. The first experiment was rather surprising. A glass cylinder placed over an electric lamp (Siemens's regulator) for two minutes, and afterwards examined, was seen to contain a perceptible amount of N_2O_4 fumes, due to peroxide of nitrogen (NO_2). The air surrounding the lamp was next drawn through a solution of potash, and the amount of nitric acid estimated; this gave 10 to 12 grains of nitric acid produced per hour (it may eventually prove to be more, the difficulty being to collect the whole of it). The next step in the research will be to examine the various forms of electric light, with a view to determine the amount of nitric acid produced by each. One of the advantages heretofore claimed for the electric light over gas light has been that the products of combustion of the former were harmless, while gas light produces the deadly carbonic acid. *Am. Exch.*

FRICTIONAL ELECTRICITY.—PECULIAR PHENOMENA.

One of our correspondents, in an early number, described his experiences, during frosty weather, of personal electrical phenomena, and, as several letters have appeared recently in *The Times* and elsewhere on the subject, it may be interesting to our readers to see the following abstract of a paper by Prof. Loomis, at the report of the twenty-seventh meeting of the British Association (1857). This paper contains an account of curious and interesting phenomena. The paper is under the title, "On Certain Electrical Phenomena in the United States," and reads thus:—"Atmospheric electricity is very abundant in the United States, and often exhibits phenomena more remarkable than are witnessed in the most considerable storms, especially in England and Germany. These phenomena are not confined to any particular season of the year, but the exhibitions in summer appear under a different form from those of winter. In summer they frequently exhibit themselves in the form of lightning during thunderstorms, and these exhibitions are often among the most sublime and impressive phenomena witnessed in any part of the globe. The telegraph wires are exceedingly sensitive to the approach of a thunderstorm. The wires are often charged with electricity from the effects of a storm so distant that no thunder is heard in the vicinity. I have often stood at such times in a telegraph office, and introduced my own body into the electric circuit, by taking hold of the telegraph wire without hand, and with the other grasping a wire which communicated with the earth. A frequent voltaic shock in the arms, and sometimes through the breast. The shock is prompt and painful, even when scarcely the slightest spark can be obtained by bringing the two wires nearly in contact. Such experiments are usually when the storm-cloud is near. If, during the passage of a thunder shower, the telegraph apparatus is left in communication with the long telegraph wires, the fine wires of the electro-magnets are almost sure to be melted and the magnets thereby rendered useless. Sometimes, in telegraph offices, there occurs an explosion, which fills the large wires, and is dangerous to human life. The effect of a feeble current of atmospheric electricity on the telegraph wires may be seen in a current from a galvanic battery. It makes a dot on the telegraph register, and when a thunderstorm passes in the neighbourhood of a telegraph line these dots are of constant occurrence, and being interposed between the dots of the tele-

graph operators, they render the writing confused and often illegible. The operators are, therefore, commonly required to abandon their work when a thunder shower prevails in the vicinity of any part of the line. Such difficulties on these lines have been overcome to a considerable extent.—[*Ed. El.*] The aurora borealis is very frequent in the United States even in summer, but on account of the long continued twilight it is not until about 10 o'clock in the evening of winter. During winter thunderstorms in the United States are of very rare occurrence, but even at this season they are not entirely unknown. Sometimes in midwinter, after a series of unusually warm days, a strong wind suddenly springs up from the west, attended by a shower, during which several flashes of lightning, accompanied by thunder, are noticed. Such a shower is invariably followed by a great and sudden fall of the thermometer, but, while electrical discharges in the form of lightning are rarely witnessed in winter, other electrical phenomena of great interest are of almost daily occurrence. These phenomena consist of free electricity manifesting itself in bodies resting on the earth, but sufficiently insulated. This free electricity is particularly noticeable on the clothes and hair of the human body. During cold months of winter, the human hair is commonly electrified, and the degree to which it is charged with a fine comb. Often at such times the fine hairs are seen to stand erect, and the person can comb to make them smooth the more obstinately they refuse to keep their proper place. If you wish to present a person to be electrified in a dry room, give him a book, like a lack of dry hair attached to the prime conductor of an electrical machine. In such cases there is but one remedy—the hair must be thoroughly moistened, after which it flies quietly in its place. During the same season of the year all woollen articles of clothing become highly charged with free electricity. The pantaloons, in particular, are found to attract light feeding particles of dust, down, &c., especially near the feet, and it is impossible to cleanse them by brushing. The longer you brush the more your clothes are covered with dust and lint. Nothing less than a wet sponge is sufficient to cleanse them. At night, when you take off your pantaloons, you hear a distinct crackling noise, and in a dark room perceive a succession of flashes. You draw your fingers down over them, especially near the lower extremities, and you perceive a repetition of the crackling noise, accompanied by distinct flashes of light. As you take off your flannel drawers the crackling is again heard, louder than before, and the flashes of light are more vivid. If you take a woollen blanket from your bed, hold it suspended in your hand, and draw the fingers of your right hand over it, the crackling is equally loud and long continued. Your fingers seem enveloped in a shoal of light, and the flashes can be several times renewed. Brute animals do not escape the general electrical influence. In a cold frosty night, put down your loud gentle cat when she is purring most loudly, and you hear a distinct crackling noise, while her consent to play the philosopher with you. Persons riding on horseback during a snowstorm in the night have frequently noticed the extremities of their horse's ears tipped with light, like that of a pitch, steady flame. The preceding phenomena are either unknown in this country, or are only noticed occasionally, and in an inferior degree; but the aurora borealis is often witnessed in the United States, and is frequently attains a splendour such as is surpassed in but few portions of the globe. During the severity of winter, and especially in houses which are furnished with heavy carpets and kept thoroughly warmed, even more remarkable electrical phenomena are often witnessed. If you walk across such a carpet with a slight shuffling motion, and then present your knuckles to some metallic object, as the knob of a door, you perceive a decided shock and a faint spark. By walking rapidly two or three times back and forth the spark may be increased, and becomes, perhaps, a quarter of an inch or more in length, and has great intensity, accompanied by a smart snap. This phenomenon is not confined to any particular house or style of carpet, but in the cold months can be witnessed in almost every house in New York where there is a thick woollen carpet, and the room is kept habitually well-heated and dry. In some houses these phenomena are so remarkable that persons who have never witnessed them have listened to the accounts with evident incredulity. A few winters ago I received from a female friend an account of some phenomena which she had witnessed at the house of Mrs. C., in New York, and which appeared so remarkable that I concluded the account must be greatly exaggerated. I was induced to call on Mrs. C., and request her to favour me with an exhibition of her electrical powers, to which request she very politely acceded. We were sitting in a parlour covered with a heavy velvet carpet, and lighted with gas by a chandelier suspended from the ceiling. Mrs. C. rose from her chair, advanced one or two short steps, and gave a slight spring towards the

chandelier, which was above her reach when her feet rested upon the floor. As she approached the gas she held the metal I perceived a brilliant spark, and heard a snap much as would have attended the discharge of a small pistol. Immediately walking through the hall, separated from the parlour by a closed door. The spark was more brilliant than before, and the report furnished by an ordinary electrophorus when most highly excited, but its length was not so great. As the door was open the current was sufficient to repeat the electric charge, and the spark was perceived whenever Mrs. C. touched a metallic object, like the knob of a door or the ribbed frame of a mirror. The facts which had been before related to me now no longer appeared incredible, and most of them I verified by my own observations. On approaching the speaking tube to give orders to the servants, Mrs. C. repeatedly received a very unpleasant shock in the mouth, and was very much annoyed by the electricity until she learned to touch the tube with her finger. In passing from one parlour to the other, if she chanced to step upon the hearth-plate which served as slide for the folding doors, she received an unpleasant shock in the feet. A visitor who, in leaving the house, in attempting to shake hands with Mrs. C., received a shock which was quite noticeable, and somewhat unpleasant. A lady on attempting to kiss her son saluted by a spark from her lips. Her little girl on taking hold of the knob of a door received as severe a shock that she ran off in great fright. Larger children frequently amused themselves by shuffling about on the carpet, and giving each other sparks from their fingers. The preceding is the most remarkable case I have myself witnessed, but I have heard of several other houses in New York which appeared about equally electrical; and most of these phenomena here become so familiar in New York that they have ceased to excite surprise. The electricity thus developed exhibits the usual phenomena of attraction and repulsion, and is capable of igniting combustible bodies. By skipping a few times across the room with a shuffling motion, and, then presenting the knuckle to an open gas-burner, the gas may be ignited.

this experiment generally fails unless the burner be warm; but if, after a jet has been some time burning, you extinguish the flame and then draw a spark with your knuckle from the warm burner, the gas is readily ignited. After a careful examination of several cases of this kind, I have come to the conclusion that the electricity is excited by the friction of the shoes of the invalid upon the carpets of the house. I have found, by direct experiment, that electricity is developed by the friction of leather upon woollen cloth. For this purpose, I stood upon an insulating stool, and, spreading a small piece of woollen upon a table before me, rubbed a piece of leather vigorously upon it, and then, bringing the leather near the copy of a gold-leaf electrometer, found that the leaves were repelled with great violence. The electricity of the leather was of the resinous kind. Electricity must, therefore, necessarily be excited wherever a person walks with a shuffling motion across a carpet, but it may be thought remarkable that the electricity should be intense enough to give a bright spark. In order to produce the highest effect there must be a combination of several favourable circumstances. The carpet, or, at least, its upper surface, must be entirely of wool and of a close texture. From my own observations, I infer that heavy velvet carpets answer this purpose best. Too thick-ness of ingrain carpeting answer very well. A dragget spread upon an ingrain carpet yields a good supply of electricity. The effect of the increased thickness is obviously to improve the insulation of the carpet. The carpet must be quite dry, and also the floor of the rooms, so that the final drying and the vegetable gas soon as it is excited. These conditions will not generally exist, except in winter, and in rooms which are habitually kept quite warm. The most remarkable cases which I have heard of in New York have been in well-built houses, kept very warm by furnaces. The furnaces are erected in the cellar, and are filled with anthracite coal, which is kept constantly burning from autumn till spring. The heat is then conveyed to the hall, the parlours, and to every room in the house, so far as is desired. Through large flues built in the walls, the fires having a section of about nine inches square. Such flues the wood during winter becomes very dry, and all the furniture shrinks and cracks. The electricity is most abundant in very cold weather. In warm weather only feeble signs of electricity are obtained. The rubber, i.e., the shoe, must also be dry, like the carpet, and it must be rubbed upon the carpet somewhat vigorously. By skipping once or twice across a room with a shuffling motion of the feet, a person becomes highly charged, and then, upon bringing the knuckle near to any metallic body, particularly if it have good communication with the earth, a bright spark passes, and a sharp snapping sound is heard. If furnished with a thick woollen carpet, and in a room which is and dry, a spark may thus be obtained in winter, but in some rooms the insulation is so good that it is impossible to walk across the floor without exciting sufficient electricity to give a spark.

Electrical Phenomenon

I HAVE just read in NATURE, vol. xiv. p. 230, an account of a strange electrical phenomenon observed at Teignmouth. In connection with it the following incident may be of some interest:—When in Switzerland, last spring, I was visiting one of my friends the manse of Mörel, in the Upper Valais. It was late in the evening, and on gaining the summit we saw a thunderstorm advancing from the direction of the Italian valleys, and not wishing to be soaked to the skin on the long descent we deemed it best to turn our steps homewards. We had not traversed a very short distance along the ridge when the storm-clouds swept up upon us; the flashes were fall so thick that we could hardly see one another, and we were all suddenly attracted by a peculiar hissing sound, which I at first thought was caused by the rain falling upon the thunder-cloud, and we fled from the top of it. Looking through which the ground electricity was flowing off into the cloud; if it had been dark, the whole thing would have been a most beautiful sight. As it was, it was grand enough. I do not remember what month it was, but I think it was in August or September. When the phenomenon was observed, I forget.

Alta Terrace, Manhattanville, York.

W. S. GREEN

Electrical Phenomena

MR. GREEN, in his letter to NATURE, vol. xiv. p. 230, omits to state the route by which he ascended Monte Rosa "not long since." This is a detail of interest, because the rocks of that range are decidedly magnetic, and, much hidden on the north side by ice.

In 1825, much out of sorts, I was ailing by short climbs, and at the Kuffelberg, well known for its effect upon the magnet, strolling up the Gorner Grat in company with three other members of the Alpine Club, and several more, the sky quickly clouded over, it thundered, and the axe of the Alpine stock fizzed in most orthodox fashion, especially when held up, and the long sticks of the non-climbing men also crackled. A transitory but vivid lightning storm followed.

Several days later, during an attempt to ascend the Stockhorn, in company with a young Englishman, from the north side, by the Triftje glacier, the same fizzing, concurrently with a strong thunder, and lightning, took place, and half up the last glacier a thunder storm came upon us, and throwing caution to the winds, we both sheltered down the snow and ice slopes with great respect for crevasses, but never part with your axe," we were much inclined to throw ours on one side. Soon we got below this critically charged stratum of the air and earth, and the fizzing ceased. I shall never forget that terrible half-hour, only to be imagined by mountaineers or mariners. Forbes, in his splendid work on glaciers, relates a similar incident somewhere in this same range.

Positive and negative charges of earth and air, combustibility of these and of axes, and laboratory experiments suggest themselves. In our later cave all were more than dosy.

I have not Forbes' book here, and can therefore give no details. Thunderstorms are characteristic. In 1859 (I think) I was 4 weeks at the Grimsel, called the Nova Vlaco Yber. Does head it was fine. A mile below was a thunderstorm, and during our descent on the Italian side, we came into it, and were refreshed first by snow, then by rain, till we reached Meiringen.

MARSHALL HALL.

Verner-Montreux, Canton Vaud, Switzerland, January 27

ELECTRIC LUMINOSITY OF GASES.—M. Gillard Wiedemann from experiments made by passing discharges from a Ruhmkorff induction-coil excited by two Bunsen cells through a tube filled with air, has determined that a current will become electrically luminous by the passage of sufficient strength, while yet at a temperature far below that of C., indeed, 65° C. is not the lowest temperature at which a gas may emit light under this condition.

ELECTRICAL PHENOMENA DUE TO ETHER.—Within the last few years Professor J. Clerk Maxwell has shown the possibility that all electrical phenomena are due to pressure in the same ether, and this has long been assumed as the means of the propagation of light. Acting upon this assumption he has deduced what the laws of transmission of light in ordinary crystalline and magnetised media would be, and from such deductions he arrived at the laws of those phenomenon. In a Paper recently read before the Royal Society, Mr. G. F. Fitzgerald, F.T.C.D., investigates the laws of the reflection and refraction of light upon the same assumption, and he has obtained the same results as Professor MacCullagh long ago deduced from his theory, and which are known to represent almost exactly the laws of reflection and refraction at the surfaces of ordinary and crystalline media. Still further, he investigated the laws of reflection at the surfaces of magnets, with theoretical results which essentially agree with and completely confirm Mr. Kerr's recently-published experiments on the reflection of light from the pole of a magnet.

NOTE

SUR L'ÉTUDE DES ORAGES ACCOMPAGNÉS DE GRÊLE ET DE PHÉNOMÈNES ÉLECTRIQUES.

La formation de la grêle, les diverses causes qui peuvent y contribuer, sont des questions très intéressantes et encore très obscures de la météorologie, et toutes les théories émises depuis un siècle laissent beaucoup à désirer. Rien l'état actuel, il convient surtout de réunir des observations nombreuses et exactes sur les faits principaux.

M. Colladon indique les questions suivantes :

1° Dates aussi exactes que possible et rendues comparables avec l'heure de Paris, de Berne, ou de Genève, du commencement et de la fin de la grêle; la largeur de la surface grêlée?

2° Dimensions moyennes et maximes des grêlons, leur forme, le nombre moyen ou maxime des couches qu'ils présentent; les couches successives augmentent-elles d'épaisseur à partir du noyau central?

3° Forme apparente et élévation des nuages à grêle; présentent-ils l'apparence d'un vaste mouvement giratoire continu, ou seulement des mouvements d'attraction et de répulsion; multiplicité des éclairs, leur nombre moyen par minute; sont-ils, ou non, accompagnés de bruits retentissants et de chutes fréquentes de la foudre sur le sol, ou sont-ils pour la plupart muets? existe-t-il des chutes notables de grêle sans phénomènes électriques apparents bien marqués?

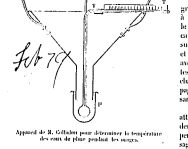
4° Température moyenne de l'air avant ou pendant un orage électrique et température de l'eau de pluie qui l'accompagne au moment même de sa chute.

Cette température de l'eau de pluie pendant les orages d'été, est une des données intéressantes à constater. M. Colladon a fait construire un appareil peu coûteux qui remplit le but proposé; il se compose d'un thermomètre à minimum (T,T) recourbé en équerre, fixé sur un entonnoir dont l'axe est vertical.

Ce thermomètre est gradué sur sa partie supérieure horizontale, le bas de la tige et la boule traversent l'entonnoir dans une position verticale qu'on coincide avec son axe, la boule qui dépasse l'extrémité inférieure de l'entonnoir est logée dans un petite capsule (P) où se rend l'eau de pluie.

Un filet (F) placé au-dessus de l'entonnoir garantit le thermomètre contre la chute des grêlons. (Voir la figure ci-contre, 1/3 grandeur naturelle.)

M. Colladon rappelle que, lors des très violents orages de grêle des 7 et 8 juillet 1875 (*Comptes rendus de l'Institut* des 6 et 13 septembre) des défâts immenses se succédaient à une fraction de seconde; mais presque tous étaient muets et ils ne



Appareil de M. Colladon pour déterminer la température des eaux de pluie pendant les orages.

furent accompagnés d'un une chute de foudre constatée sur le sol.

Au contraire, l'orage de grêle qui, le 3 juin 1877, à 6 h. du soir, a traversé le canton de Genève et causé de grands dégâts sur les cantons de Vaud et de Fribourg, a coïncidé avec de nombreuses chutes de foudre sur le sol et chaque éclair était accompagné d'éclats retentissants.

Des observations très attentives pendant ces deux orages et postérieurement ont appris à passage de la colonne de grêle, n'ont laissé sur aucun mouvement giratoire dans la masse nuageuse d'où tombait la grêle.

Huit lieues l'orage qui a traversé, dans la nuit du 7 au 8 juillet, le canton de Genève a laissé d'innombrables traces de son passage; partout ces traces donnent des directions semblables et parallèles pour le chute des grêlons et la direction du vent sur tout le territoire qui a été frappé.

Sur une largeur de 7 kilomètres et une longueur de 25 kilomètres plusieurs centaines de maisons portent encore les marques très visibles des coups frappés par les grêlons contre les façades et toutes, sans exception, ont été frappées du côté ouest-sud-est au-delà du canton, dans les départements de l'Ain et de la Haute-Savoie, l'orientation des traces de la grêle est encore la même, ce qui ne permet pas d'admettre un grand mouvement giratoire de ces grêlons, ni même des nuages d'où s'échappait la grêle.

A New Phenomenon in Statical Electricity.

M. E. Duter, in a paper read before the French Academy in December, showed that when a Leyden jar is charged with either positive or negative electricity its internal volume increases, and that this effect is a new phenomenon, unexplicable by either a theory of an increase of temperature or of an electrical pressure. The experiment was performed by means of a flask-shaped Leyden jar with a long tube attached to its neck, and containing a liquid which served as the inner armature. The author's attention had been called to the fact that this phenomenon had been observed ten years ago by M. Gore.

His researches, just made public, leave no doubt of the accuracy of M. Duter's view, that the glass of the jar really expands. According to the theory of elasticity, the effect of an internal charged with a hollow sphere is in the inverse ratio of its thickness. M. Duter, therefore, had three flasks made of the same volume, but of thicknesses of 4 mm., 9·3 mm., and 0·5 mm. respectively. They were filled with water and enveloped by tin foil. Each carried a capillary thermometer tube, in which the variations of the height of liquid served to measure the changes in volume due to electrification. He found that these changes were inperceptible in the thick glass, very marked in the flask of mean thickness, and rose to 30 mm. in the thinnest. The variations in volume were very nearly in inverse ratio of the square roots of the thicknesses.

English Mechanic & World of Science July 22nd 1881

Appareil pour expérimenter l'action de l'électricité sur les plantes vivaces (1).

L'appareil consiste en une grande cloche dans laquelle on fait arriver l'électricité obtenue de la façon suivante :

On place un vase métallique sur un support de 2 mètres de haut où il est isolé pour que l'électricité ne se perde pas. On remplit ce vase d'eau. Quand on laisse l'eau s'écouler par un tube très-étroit, le vase se charge continuellement d'électricité positive en temps ordinaire, c'est-à-dire l'électricité atmosphérique dans l'air. Si au contraire, au contraire, d'électricité négative, dans les cas peu fréquents où l'électricité atmosphérique est négative.

« Ces phénomènes, que M. Palmieri appelle la *veine liquide descendante*, ont été découverts et étudiés par lui en 1850, et décrits dans un Mémoire présenté à l'Académie des sciences de Naples. Dans ces dernières temps, M. Thomson a cru pouvoir se servir de ces faits pour mesurer la tension électrique de l'air.

« Un fil métallique est placé à ce vase que nous appellerons *collecteur* il pénètre dans l'intérieur d'une cloche de verre, où il

(1) Note présentée à l'Académie des sciences dans la séance du 22 octobre, par M. Berthelot, au nom de M. Cell.

se relie à une couronne de pointes métalliques très-aiguës, destinées à distribuer l'électricité. On place, sous cette cloche, les plantes dans des vases qui sont en communication avec le sol. Pour fermer hermétiquement, on fait passer la cloche sur une plaque de verre rodée; elle porte des tubulures par lesquelles on peut faire entrer et sortir l'air au moyen d'une trompe. D'autres plantes identiques sont placées sous une cloche semblable à la première et de même capacité, mais dans laquelle ne pénètre pas l'électricité atmosphérique.

« Le 30 juillet dernier, on sema trois grains de maïs, en prenant des grains de poids égaux pour chaque cloche et de la même terre. De plus, chaque vase reçut la même quantité d'eau. Le 1er août, les graines commencèrent à germer ; pendant deux jours, l'accroissement fut à peu près le même dans les deux cloches. Le troisième jour, les plantes de la cloche dont l'air était électrisé commencèrent à se développer plus rapidement que celles de l'autre cloche. Le 10 août, on mesura les plantes, qui ont les dimensions suivantes prises de la base de la tige à l'extrémité des feuilles supérieures :

Plantes dans l'air électrisé.....	17 c.
Plantes dans l'air non électrisé.....	8

« M. P. Palmieri a entrepris, au laboratoire de l'École supérieure d'agriculture, des recherches relatives à la composition de l'air dans chacune des deux cloches et à la composition de nues dans les conditions ci-dessus énoncées. »

—

New Phenomenon of Voltaic Electricity.

M. Reinold Kerr sends to the *Stiatly Journal of Science* an account of a very interesting experiment by Mr. Sleginoff, which is likely to be fruitful in physical research. He takes, as the two electrodes of the battery, a thin platinum plate, placed horizontally to the plate, and nearly in contact with it. A small quantity of water acidulated with sulphuric acid is poured onto the plate. If a current from a battery of 8 to 10 cells be passed through this arrangement, a spot of light is observed on the point of the wire where this constitutes the cathode. With fifteen couples this quadruplicates the cathode, the direction of the current is reversed. During the phenomenon the water is only slightly decomposed, and the needle of a galvanometer introduced into the current is only slightly deflected. It was also remarked that the surface under the water of the wire is depressed, taking the form of a cup. The bubbles of gas arising from the decomposition of the water, in this case, travel constantly round the wire, forming a very pretty figure of 8. It was further discovered that during these actions in the apparatus the current is intermittent.

Selenitic Ether.

A MEMOIR, published by M. Pauli with the French Academy of Sciences on June 13, 1877, has been opened by that body and found to contain the author's researches on currents of high tension. These studies tend to prove, in the author's view, that the electric discharge consists of a movement or transport of a very small quantity of penetrable matter at a very high velocity.

From experiments made by passing induction currents from *liquid* electrodes through Geissler tubes, Herr Paulson is led to doubt whether a plurality of spectra is to be obtained from the same gas under different conditions of pressure and temperature.

According to M. Henri Becquerel, in the *Comptes Rendus* for Jan. 29, base of nickel become saturated with magnetism much more promptly than iron bars, and hence are better suited for magnetization —a fact which might be useful in telegraphy. Cobalt gives results similar to nickel.

Animal Electricity. 19

In a remarkable lecture delivered before the Medical Society of Zurich, on February 2nd, 1876, and published in *Nature* for April 17th, Dr. L. Hermann summarizes that "the whole of the electrical phenomena of muscle and nerve may be readily deduced from a very few simple proportions. Irritable protoplasm responds both to destructive and to exciting influences by an electro-motive sign. The altered substance takes on a negative potential with respect to the unaltered. This, together with the doctrines of internal transverse polarization, and of the polarizational increment of excitation, appears fully competent to explain all the facts hitherto observed.

45

OBSERVATIONS EXPÉRIMENTALES

M. Villari a envoyé à l'Académie des Sciences une communication fort intéressante sur les lois thermiques et galvanométriques de l'étincelle électrique.

L'auteur a réalisé ces expériences à l'aide d'un thermomètre particulier de son invention et trouvé des lois identiques à celles qui étaient démontrées pour les décharges dans les circuits métalliques.

On peut dire que ces effets sont proportionnels aux quantités d'électricité employées et aux longueurs des circuits reliés.

Ces curieuses déterminations sont une confirmation des idées sur l'unité du mode d'action des fluides électriques, quelle que soit leur origine. Elles sont de nature à soutenir les idées précoces des électriciens qui ont été si longtemps des adversaires de la division de la lumière, et qui, si nous sommes bien renseignés, sont en train de se convertir à des idées plus exactes.

Nature Aug 19 1880

Magnetic and Earth-Current Disturbances.

IT may be of interest to point out that a magnetic disturbance has just been experienced at the Royal Observatory greater in magnitude than any that has occurred for some years.

On August 11, at 10.30 a.m., active disturbance suddenly commenced, and continued until midnight, recognizable, as usual, by the exhibition of earth currents. The magnets were then generally quiet until about noon of August 12, when disturbances of still greater magnitude began to be shown, continuing till 6 a.m. of August 13. During the latter period the variations in the magnetic declination and horizontal force were frequent and large, especially between noon and 4 p.m., and between 7 and 9 p.m. Between noon and 4 p.m. there was also a considerable appearance of vertical magnetic force. During the whole period, from noon of August 12 to 6 a.m. of August 13, earth-currents were unusually active and strong, especially during those times at which the magnets are most disturbed.

It seems well at the present time to call upon our engineers, and especially those concerned in the laying of telegraph cables, that disturbances of the character of that described above are now become not unfrequent as compared with the existence of recent years. I may perhaps be permitted here to refer to a short paper, "Notes on Earth-Currents," to be found at p. 211 of vol. viii. of the *Journal* of the Society of Telegraph Engineers, as containing information on the question of magnetic disturbances and earth-currents, probably not without interest at this time.

WILLIAM HUGGINS

Royal Observatory, Greenwich, August 14

P.S.—During the evening and night of August 13-14 large magnetic disturbances again occurred, accompanied as before by strong earth-currents.

Scientific American, Sept 24, 1881

An Electric Storm at Sea.

The German war schooner Nautilus reports passing through a singular storm while crossing the South Pacific from Tahiti to Sydney, Australia.

On the afternoon of May 11, the whole heavens appeared to be enveloped in cloud, which made it so dark that the crew could scarcely see the length of the ship. The thunder became deafening, and the flashes of lightning almost blinded the sailors' eyes. All around the vessel the light ning was striking the water, so that persons on board expected the vessel itself would be hit. But this they were spared. The effect, however, was singular and grand, and at times the vessel appeared to be in flames in several places at once. Balls of lightning on several occasions fell in the water within 20 or 40 yards of the ship's side. While this peculiar storm lasted very little rain fell and the sea was almost entirely still.

A PECULIAR SPARK DISCHARGE.

WHEN electricity from the induction apparatus consist of a point and a metallic plate, the striking distance of the spark produced is considerably greater if the point form the positive pole and the plate the negative, than if the point be negative and the plate positive. With the latter arrangement, under certain conditions, Herr Haskel (of the Leipsic Society of Science) has observed that the sweeping spark first from the negative point *positive* electricity may pass over in long sparks to the opposite plate.

To the pole of an induction apparatus, which is positive for the breadth of from about a foot was attached, and opposite to it was fixed a brass plate, underneath, which, with the negative pole of the apparatus, was connected to earth. With this arrangement, three pencil, at an interval of from zigzag sparks from the point to the plate, which, however, were not uniform, a break discharge took place from the point. The point being then, by turning the micrometer-screw, made the negative pole of the induction apparatus first passed (the primary current having been interrupted) at an interval of 80mm. When the point was removed further from the plate there appeared only radiations. The sparks which appeared at 55mm. interval were zigzag in form, thin, and without much sound, and they continued so till the interval was contracted to 50mm. Then the spark altered in its nature, it became pretty straight, and produced a more decided sound.

The peculiar aspect of the spark between 55mm. and 50mm. interval suggested the idea that positive electricity was carried over, and the insertion of a Holtz's jar was employed for this fully. By other means, as directly with the electrometer it was demonstrated, that with an interval between the point and the plate of from 55mm. to 50mm., there passed from the point which was negative at the break of the primary current positive electricity, whereas with a less interval of spark negative electricity passed.

For this interesting phenomenon, which the author intends to study further in its details, he offers the following explanation:—

The opening of the circuit of the primary coil at first lessens the tension of the so-called negative pole, negative electricity. If now the distance of this point from the opposite plate be greater than 55mm. the negative electricity cannot pass in sparks; but the tension which immediately thereon exists between the induction wire, and which now brings positive electricity to the previously negative point, has not power enough to discharge this positive electricity in sparks, because the tension produced by the backward oscillation (Rückschwingung) is greater than that produced by the first direct impulse at break of the primary (this was especially the case in the experiments with a length of 55mm.). When the interval at the negative pole is approximated to a distance of 50mm., from the plate, still the negative electricity driven to the point by the break of the primary circuit cannot pass over in sparks, but the positive which thereupon comes to the point from the earth falls on it with less opposition:—

The spark now appears, because the tension of the positive electricity in

La pêche à l'électricité

Ayant renoncé à l'espérance de relever le *Vanguard*, qui s'était coulé il y a trois ou quatre ans par l'Iron Duke, sur les côtes d'Irlande, le gouvernement britannique a pris la résolution de faire sauter l'épave avec de la dynamite. Cette mission difficile a été confiée au *Volunteer*, qui s'en est acquitté à l'aide de torpilles explosionnées, à l'aide de l'électricité.

Les effets ont été extraordinairement énergiques, comme on s'y attendait; mais ce que l'on ne prévoyait point, c'est l'énorme quantité de poissons de toute nature qui avaient été foudroyés et qui furent trouvés flottants à la surface de la mer. Les marins de l'équipage du *Volunteer* auraient pu faire une pêche si abondante que le pont en aurait été encombré

Pêche miraculeuse produite par l'action de l'électricité mettant le feu à des torpilles.

s'ils avaient ramassé tous les cadavres flottants dans le voisinage du navire.

Nous avons cherché à peindre la scène qui se passa à bord quand le cuisinier des officiers vint choisir dans le tas les poissons qui lui convenaient.

Un peut conclure de la richesse de cette pêche miraculeuse, que les torpilles pourraient être parfaitement utilisées, lors du passage d'un banc de harengs ou de morues sur un fond. L'essai n'a point encore été tenté; aussi il mériterait d'attirer plus spécialement qu'il ne paraît pourvoir être prévenus télégraphiquement ou par pigeons du l'arrivée prochaine des poissons dans les parages qu'ils fréquentent.

C'est à l'incompressibilité presque absolue de l'eau qu'est due l'énergie de cette action destructive, car les poissons reçoivent ainsi un choc équivalent à un coup de marteau, dont l'énergie décroît en raison inverse du carré de la distance au centre d'ébranlement.

Si l'on voulait employer pratiquement cette méthode, on devrait répartir sur un espace plus ou moins grand un certain nombre de foyers.

L'expérience seule indiquerait la masse de dynamite qu'il faudrait employer à chaque centre d'explosion, masse qui serait plus ou moins grande celle-ci étant suivant la profondeur de l'eau.

La condition la plus essentielle à remplir, pour arriver au maximum d'utilisation, sera la simultanéité absolue de l'explosion.

Aurora Borealis and Magnetic Storms

THE epoch of great auroras and magnetic storms has again returned, as was evident from the fine displays seen here on the evenings of the 11th and 12th, and these are as usual accompanied by an increase in the number and size of the sun-spots, and in the developement of the solar prominences. The aurora on the 11th was grand, but that which followed it on the 12th excelled greatly the magnificent display of 1869, 70, and 71.

On the 12th my attention was first called to the phenomenon at 10h. 25m. p.m., when the northern horizon was skirted by a bright white fame terminating in an undefined arch, from which results. The bank of white light on the horizon extended from about 32° E. of N. to 40° W. of N., and none of the streamers attained an altitude of fully 60° at 26h. The brilliancy of the individual streamers was varying rapidly, but there was little variety in the character of the phenomenon.

At 11h. 30m. the brightest streamers were W. of N. Ten minutes later this brilliant white band of light had spread gradually westward, and was some 25° W. of N., when it faded away. Some streamers were still more W. of N., and others again were slightly E. of N.

At 11h. 40m. there was nothing remaining of the aurora except a cloudy whiteness in the north, the seat of the heavens being a deep blue. A minute later streamers were again apparent.

At 11h. 45m. a very bright streamer formed 5° E. of N., and then a similar band of light appeared 5° W. of N., followed in rapid succession by other streamers 10°, 20°, and 45° W. of N., each streamer fading away before the succeeding one became very bright.

At 11h. 50m. a single narrow band of intense white light stretched from the horizon towards the zenith, passing through Cor Caroli.

At 11h. 52m. the light in the N. and N.N.W. again heightened up, but there was no further appearance of streamers.

The magnetic storm that accompanied the aurora of the 12th was one of the most violent ever recorded at this observatory, and was very similar in character to the magnificent storm of 1869.

On the evening of the 11th the magnetic needle was very irregular in its movements, but it was only towards midday of the 12th that the storm really began. The oscillations from the beginning were very rapid and extensive. The first great movement began at 11h. 30m. p.m., and between 11h. 45m. and 12h. 20m. the declination magnet moved 1° 6′ 45″ eastward. They returned westward, and at 1h. 20m. the reading had increased by 1° 18′ 15″. Between 7h. 50m. and 8h. 20m. p.m. the needle moved 1° eastward, but it attained its extreme E. position slowly and quickly towards the west, and after a double sweep it reached its maximum at 8h. 13m., the change of declination in 4m. being 1° 27′ 30″.

The oscillations of the V.F. magnet were as great as those of the declination. The chief sensitives occurred at 5h. 40m. p.m., and there were three marked minima at about 10 p.m., midnight, and 2 a.m., the two latter of which were lost from the oscillation being too great to be recorded. The horizontal force was also in the first hours a decrease of 1 in lock of ordinate in 5m.

The variation of the H.F. magnet was very large, but not so remarkable as that of the V.F.

On the 13th the magnetic storm continued greatly to disturb all the magnets, but it was less violent than on the preceding day.

Stonyhurst Observatory, August 15 S. J. PERRY

THERE was a beautiful display of the aurora here last night. Between ten and eleven o'clock the streaks extended from the horizon to the zenith. The colour was principally pale blue, but a reddish tinge was occasionally discernible. I observed what I thought was a distinct movement of some of the streaks. A bright comet suddenly made its appearance to the westward of a small black cloud, seemed for some slowly eastward and disappear. There was a slight breeze from the east at the time, but I do not think that the clouds were moving sufficiently rapidly to account for the phenomenon.

Springburn, Glasgow, August 13 J. A. B. OLIVER

A Case of Slow-Sub-Tepical Discharge of Earth-Electricity, and the Sun Recognisant thereof

In the course of yesterday afternoon, in the midst of a sky otherwise clear and exquisitely blue, a large cloud of unusual shape and character began to form in the upper regions of the atmosphere vertically over, but very far above, the southern slope and even most elevated mountain tops of Madeira, and continuing there, as it did, most fixedly more than half the day, so contrary to the locomotive habits of ordinary clouds, it soon attracted the attention, and presently the fears, of most of the inhabitants.

As seen from this place, between 1h. and 3h. p.m., there was little more than a single dense cloud of peculiarly rounded outlines and somewhat elliptical figure, stretching from the western horizon to within 20° or 15° of the zenith, but no sign advanced.

Shortly after 3h. p.m. this cloud was seen to be divided into two, the first, having symmetrical and evocentric outlines thereafter, while the central vertical axis, which might be conceived as passing through the whole series, remained unchanged and fixed in space. The central fairly, too, of them all continued, together with the infinite concealments of the outlines of all the smaller lower terms of cloud, although the largest and uppermost one visible to us began to put forth a variety of fringes of silver-cumulus character; and, as tested by the spectroscope before sunset, all the lower smooth-massed clouds were remarkable for the large quantity of watery vapour they contained, and held fast too, for so rain fell. As sunset approached every one was gazing at the strange phenomenon of a cloud-congeries of most portentous size and absolute fixedness in the trade-wind, probably also the anti-trade region; and when at sunset the most gorgeous coloured illuminations through all the range of reddened, red, crim-crowned, silvered, red dun shadowed and grey passed from manifer to member of the series, although, as the various heights of its strata rose above the other; while the centrality of the general height was shown, even long after darkness had fallen, by a faint lunar-like illumination of the northern outline of the whole, that by ten o'clock this began to fall, and the system of superposed clouds was beginning to contract in its central axis, and faded away, without having its place, before morning.

In so far we had been witnessing, though without any positive light of its own, a vertical series of disks of cloudy matter, extremely like the lower end of the successive, transverse, di-cone arrangements seen in a gas vacuum-tube of large dimensions, when the electric discharge from a powerful induction-coil is passing through it; and we were inevitably remi-ded thereby that the accepted electric theory of M. Gaston Planté (of "secondary batteries or storage" fame) justifies an escape of the earth's inverse electricity from time to time into planetary space, and more particularly to the sun.

What there, however, in this case was symptom of the sun receiving or falling for, my such discharge, and from this part of the earth?

The sun was undoubtedly in the Northern Tropic, and the highest northern declination of the sun had just been reached; but for a fortnight or more past the solar spot manifestations had generally been weak, almost fading away, for the most part well, leaving taken a picture of the sun-spots every day (Sunday excepted) since I have been here. However, though the appearances were not so great as they could be on June 21, 22, and 23, yet on Friday, June 24, there was a little improvement, some new, though small symptoms appearing in either solar tropic. On Saturday, June 25, these new features were confirmed and slightly increased. But what were they on Sunday, June 26, when the extraordinary cloud-arrangement was hanging so long above Madeira?

I, who am here merely as a private amateur in a different subject, know only too well on Monday morning, early at 9h. 30m. a.m., I was astonished and delighted at the solar scene then presented. The spot—the principle sight of on Friday were now well advanced and much developed: a new group with extensive double ramification had also appeared in the same tropic nearer the equator; while finally, near the middle of the sun's disk in the same tropic, were two large spots, with connections extending over 60,000 miles in length of solar surface, and indicating more extensive changes to have been developed, if not suddenly revealed within the last forty hours, than anything which I, at least, have witnessed for a very long time past.

LA NATURE

L'ÉLECTRICITÉ

REVUE SCIENTIFIQUE ILLUSTRÉE

BEAUX-ARTS — INDUSTRIE — MARINE — ART MILITAIRE — MÉDECINE

2e SÉRIE — N° 13

5 JUILLET 1879

LES GRANDS PHÉNOMÈNES ÉLECTRIQUES

Les Orages

Nous avons signalé, dans notre numéro du 3 juin, la négligence extraordinaire des météorologistes réunis à Rome, qui ont oublié d'éclairer leur lanterne; car, aucun de ces savants officiels n'a paru s'apercevoir que l'électricité était la plus importante des spécialités dont ils eussent à s'occuper s'ils tenaient à gagner leur vie d'une façon plus sérieuse qu'en rédigeant des prédictions que les augures de l'ancienne Rome d'amusant jamais consenti à signer.

On dirait que les forces brutales de la nature ne sont point si avengles qu'on veut bien le dire et qu'elles prennent un malin plaisir à montrer l'insuffisance des théories à l'aide desquelles des hommes à courte vue s'imaginent lui avoir arraché ses secrets.

En effet, il y a longtemps que les orages n'ont été si fréquents, si terribles, non pas seulement de ce côté de l'Atlantique, mais encore dans un autre continent.

Nous ne pouvons entreprendre du discuter toutes les circonstances bizarres qui se sont produites cette année et que les journaux politiques des différents pays ont relatées avec un zèle fort louable.

Bornons par l'espace nécessairement limité dont nous disposons, nous avons dû nous borner à résumer rapidement quelques circonstances qui sont de nature à éclairer la théorie des paratonnerres ou d'une façon générale quelque point particulier de l'histoire de l'électricité.

Cependant, nous manquerions à notre mission si nous ne saisissions cette circonstance pour indiquer tout le parti que la météorologie peut tirer des observations électriques que les physiciens du service international dédaignent d'une façon véritablement surprenante.

Dans nos *Eclaires et Tonnerres*, nous racontons l'histoire d'un coup de foudre qui frappa, il y a cinq ou six ans, l'observatoire de Paris et dont personne ne s'était inquiété, excepté le portier! Sans cet estimable fonctionnaire, nous n'aurions pu retrouver la trace d'un phénomène fort intéressant, précisément parce qu'il démontrait que l'Académie avait commis une erreur en ne recommandant pas de conduire les décharges des eaux pluviales jusqu'au ruisseau (1).

Avant l'invention du télégraphe, on est arrivé à décrire la trajectoire de certains orages qui ont traversé le royaume de France dans toute sa longueur. Ces grands météores privilégiés laissaient derrière eux une trace facile à suivre, un sillon de grêles marquant la trajectoire qu'ils avaient parcourue. Quelques autres parce qu'ils étaient accompagnés de trombes qui attiraient, d'une façon toute particulière, l'attention des populations.

Mais, les nuages orageux possèdent, en général, une constitution particulière qui permet, avec les moyens dont la physique moderne dispose, de déterminer leur route même dans le cas où ils ne donnent naissance à d'autres produits météoriques que de l'eau et du feu, et sans qu'ils laissent rien tomber du plus solide.

En effet, leur arrivée est toujours signalée par un rapide abaissement dans la température de l'air, par une diminution notable de la quantité de humidité qui vient du ciel, et par des mouvements plus ou moins rapides dans l'électricité ambiante.

Le plus souvent, ils sont accompagnés par des courants électriques spontanés qui se développent à

(1) C'était du temps où M. Delaunay régnait encore! Ce portier rappelle involontairement le portier de l'Observatoire de Marseille, lequel découvrit une comète avec la lunette de son maître. Ce dernier, qui était d'humeur quelquefois, se fâcha tout rouge et le portier, remplaçant du rôtire du lunette, fut renvoyé. Ce qui est encore plus grave, c'est que des astronomes français lui ont volé sa comète pour en faire cadeau à un Prussien. (Voir ce que nous en disons dans notre *Astronomie moderne.*)

ON THE ACTION OF MAGNETS ON LIQUID JETS.*

By Benjamin P. Thompson, B.A., D.Sc., Professor of Experimental Physics in University College, Bristol.

In studying the phenomena of electric tension the author has been led to inquire into the actions produced by magnets upon movable conductors, such as flames, liquid jets, flexible metallic leaves, liquid conductors, gases in high rarefaction, flames, and liquid jets, traversed by currents.

Nearly all the phenomena of rotations and translations due to electro-dynamic and electro-magnetic attraction or repulsion have been demonstrated to hold good for liquid conductors, both those which possess metallic conductivity and those which possess only electrolytic conductivity. Davy, Cassebmann, and Wolfter have shown the electric arc to behave as a mobile conductor. Plücker and De la Rive, and more recently Crookes, have observed the existence of these electrodynamic actions on the luminous discharges in highly rarefied media, and which appear to be electric convection currents rather than electric currents proper.

The author has examined the case of liquid veins, both of dilute acid and of mercury traversed by currents, and finds that they become subjected to the action of powerful magnets, exhibit analogous motions of translation, rotation, etc. Thus a liquid vein carrying a current between the

* Paper read before Section A of the British Association at Sheffield, August 20th.

poles of a horizontal horseshoe electro-magnet no longer falls straight, but is thrust aside and falls down an inverted curve. A vein falling in front of the pole of a vertical magnet is likewise drawn aside, tending to become parallel to the hypothetical Amperian currents, and to rotate in an opposed sense around the pole. Further, a liquid vein carrying a current falling upon the pointed pole of a vertical magnet is twisted, the sense of the torsion depending on the direction of the current and the polarity of the magnet. The author has also sought to extend his observations to the case of flames. He finds that the flame of the Bunsen burner, traversed by electric currents proper, but only electric convection currents, and the results obtained, though not yet completed, thrown him to include in this act of phenomena the so-called diamagnetism of flames and of jets of smoke and steam.

Alcohol by Electricity.

Berthelot's experiment was conducted as follows: "A battery of from six to eight Bunsen elements was arranged in connection with an oscillating commutator, so as to give alternately positive and negative currents twice to fifteen times a second, to two cylinders of spongy platinum, acting as electrodes. These platinum cylinders were immersed in acidulated water, and the contacts were so arranged that neither oxygen nor hydrogen was disengaged, the water being reformed as soon as decomposed. Thus regulated, the electrodes of the apparatus were immersed in an aqueous solution of glucose." In this way alcohol was formed, although in very small quantities, but it is expected that when some improvements in the apparatus are made, the process will be much more rapid.

Bibliothèque Nationale R.F.

Boston's Yellow Day.

A visit to the roof of the Equitable Building at 11 o'clock on Tuesday revealed a curious sight. To the westward vision was unobstructed by fog or haze to a distance of some ten miles. The green foliage in the interval was brilliant under the strange illumination, and the waters of the Charles River gleamed with silvery brightness. To the eastward, down the harbor, the view was unobstructed to a distance of a mile only, Fort Independence appearing to be enveloped in a light haze, and the fleet of vessels lying at anchor with the exception of the outline of the fortress. Fort Independence was an almost sharp-cut dark mass against a background of grey cloud. In all directions distances appeared to be greatly diminished, and objects near and far could be seen almost with equal distinctness, resembling little electric lamps, but being in reality the sun. On the roof of the Postoffice different operators had a portable furnace, the blaze in which, as it leaped into the air, was marked with strokes of brilliant white. Away in Scott's Baths a steam jet was visible, but the steam was not condensed, but it was not marked by the usual milky gloss of such jets. The atmosphere itself was seldom with a radiance that took all color out of other flames.

The view from the water was very strange. Looking from the landing and the piers were alike discomfited with the strange light, and the water, and the hues of the water, being supplemented by saffron, was transformed to green. The effect on the green of the field and trees was to produce a brilliant emerald. One of the greatest curiosities was the Boston Belle and Belle Isle Tubular, the chocolate color of which appeared to be transmuting into sometimes yellows fresh from the Mint. A rather effect was had from the interior of the Athenæum Library, the northern windows of which revealed the golden hue streaming through drooping willows and creepers, and the effect of the light falling a richer dye on the yellow and scarlet volumes beneath. It was remarkable that, while the green light appropriated the electric hue, the latter put on a slightly bluish tinge. An exceedingly beautiful effect was noted in a blacksmith's shop near the North Ferry, the shower of sparks from the forge and anvil being transformed from a fiery to a silver spray.

The phenomenon became more marked in the afternoon than it was during the forenoon. At late as 1 o'clock it was possible for a person situated in the middle of the Boston Belle Isle Tubular to read artificial light, but after that hour the gloom deepened rapidly. The sky grew still more lemon in appearance, and the green was that of late twilight. The front windows of stores on Washington street remained lighted all night, and there was not a single usual aspect of the city that was not lost in the yellow haze. There was something terrible in the scene, and it is not to be wondered at if some weak minds allowed themselves to be tormented by fears of what the extraordinary event might presage. The climax was reached at about 7 o'clock, and after that slight gradual improvement set in, and by 9 o'clock the yellow had entirely disappeared, the clouds had disappeared, and the atmosphere had assumed its normal condition.—*Boston Journal*, September 5.

Nature 5 Dec 1879

INFLUENCE OF ELECTRICITY ON VEGETATION

SEVERAL months ago, it will be remembered, M. Grandeau described to the Paris Academy experiments made by himself and M. Leclerc at Nancy and Meurcy, whence it appeared that flowering and fructification are retarded and impoverished if plants are excluded from the influence of atmospheric electricity—as by being inclosed in a metallic cage, or being near trees or other objects which may carry off electricity of the air.

Recently M. Naudin has repeated the experiments referred to, but with other plants and in a different climate, and, without wishing to contradict the conclusions arrived at for tobacco and maize (the plants that had been experimented with), he is led to regard the declarations made as too general, inasmuch as his results are almost exactly opposite to those obtained by MM. Grandeau and Leclerc.

It was at Antibes, in the large botanical garden formed by the late Thuret (now Government property), that M. Naudin made his experiments. He had an iron quadrangular cage made, covering a surface of fifty-one square decimetres, and about one metre in height; the frame carried points above (like small lightning conductors), and was covered with iron netting, the lozenge-meshes of this being 0·030 long by 0·024 m. broad (it intercepted more light than M. Grandeau's, but this is thought insignificant). The cage was placed in a kitchen garden, and the plants it was made to inclose were kidney beans, lettuce, tomato, and herbaceous cotton (the last alone being sown as seed). In the same garden, at 7 metres distance, plants as like the others as possible were planted, and cotton seeds of the same kind sown, but without a cage-cover. The soil was perfectly homogeneous throughout, and all parts of the plot were equally exposed to sunlight, dew, and rain. The experiment began on May 25.

For a fortnight there appeared no sensible difference between the two portions; but about the middle of June it was remarked that the plants of the cage were stronger than those in the open air, and this difference became more pronounced as time went on. The plants, indeed, progressed side by side in this sense, that the flowerings were absolutely contemporaneous in the plants of the same species; and it was the same with formations and maturation of fruits. But it was quite otherwise with the quantity of vegetable matter produced in a given time and on the same extent of soil, and this difference was entirely in favour of the caged plants.

We may take the figures tabulated by M. Naudin for the tomato (examined August 14), as a good example of this :—

	Plants in cage.	Plants under the cage.
Total weight of the plant cut at the level of the ground, fruits included	2·972 kg.	3·734 kg.
Number of ripe fruits and green fruits of all sizes ...	37	83
Weight of the whole of the fruit detached from the plant	1·80 kg.	2·162 kg.

The other plants gave a similar testimony in favour of the utilisation of atmospheric electricity. Thus, the total weights of the bean plants were respectively 2·27 and 166 gr.; and of the lettuce 137 gr. and 227 gr. The cotton plants were weakly (as there had been no watering), but their evidence was in the same line as that of the others.

The injurious influence, whence, according to M. Grandeau's theory, trees exert on plants in their neighbourhood, by withdrawing atmospheric electricity, is also considered by M. Naudin to be only a special case. Besides, it is easy to ascribe to this withdrawal what is the result of the shade cast by trees, and especially roots, which often extend to a great distance. On the other hand there are many plants which seek the neighbourhood of trees, and which even thrive only under their shadow, and these, probably, must be subjected to a diminution of atmospheric electricity. At the Villa Thuret, M. Naudin remarks, there are several lawns quite inclosed by trees (pines, firs, cypresses, &c.), many of which are adult and of pretty good size. These lawns contain, besides their grass, thousands of anemones (*A. Coronaria, A. cyanea, A. stellata*), some of pure race, others hybrid, whose flowers present all shades of red, rose, purple, white, and blue. The appearance is striking when the flowers come out in March or April. The flowering is not entirely contemporaneous throughout the lawn; it begins near the trees, and gradually extends to the middle of the lawn; the difference of time between these two extremes being twelve to fifteen days. Moreover, the anemones nearest to the trees, in addition to their relative precocity, are generally stronger and taller, and have broader, perhaps more brightly coloured corollas, than those in the middle of the lawn.

From the observations described, M. Naudin is disposed to think the question as to the influence of atmospheric electricity on plants is complex, and far from being decided as yet. This influence, in all probability, is modified first by the very essence of the species, which must behave, in regard to atmospheric electricity, as to other agents of vegetation, that is to say, in very diverse manners; then it is modified by climate, season, temperature, degree of light, dry or wet weather, perhaps also by the geological structure or mineralogical composition of the ground, the layers of which, superficial or deep, may not be equally conductive of electricity. It is possible, lastly, that all tree species may not alike withdraw the electric *effluve* of the atmosphere, and this is a point necessary to be determined. Until these numerous and so obscure conditions of the problem before us are sufficiently known, we should regard as premature any conclusion which is applied to the whole, or even only to the generality of the vegetable kingdom.

CHEMICAL EFFECTS OF ELECTRIC DISCHARGE IN GASES.

—M. Berthelot finds that both the positive and negative glow in gases do not decompose carbonic acid, as a rule, at the ordinary temperature, but that of olefiant gas, hydrogen, whether moist or dry, the discharges from a Holtz machine did not produce the slightest trace of nitrogen compounds; traces were, however, observed with discharges from a Ruhmkorff coil, but only at the highest available tensions. When the vapor of organic compounds was inclosed along with nitrogen in tubes containing a metal electrode electrified by a Holtz machine, acetylene was produced in notable quantities. The absorption of nitrogen by organic compounds is effected equally well by both positive and negative discharges, and at as well as high tensions, although more time is required for the process with low than with high tensions. With these nitrogen compounds no traces of ammonia, nitric, or nitrous acids, or hydrocyanic acid, appear to be formed. M. Berthelot has also produced absorption of nitrogen by organic compounds with the current from an ordinary galvanic battery.

THERMAL CONDUCTIVITY.

—Dr. Lodge described a simple form of apparatus for determining the thermal conductivity of non-substances, such as crystals, which cannot be obtained in slabs or rods. It consists of two small tin cans with a copper arm about 6 inches long projecting horizontally from each, the external ends being very clean and flat. They are placed in a straight line with the crystal between them, and held together by a slight horizontal pressure. Holes are drilled in the copper rods for thermometers, and the curves of temperature being given by these, that for the intermediate crystal can be at once calculated.

THE GRAMME ELECTRIC LIGHT MACHINE

has recently been tried at the Palais de l'Industrie, Paris. A space of 12,000 square metres in area was brilliantly illuminated by two electric lusters, each of six lamps, and placed two observers feet above the ground. The machines were driven by two steam engines of 35 horse-power each. It is estimated that 1000,000 candles would be required to give the same lighting power.

Encore les Étoiles filantes

L'Éternelle

Comme nous avons été conduits à nous plaindre amèrement de l'état d'abandon dans lequel on laissait les observations d'étoiles filantes en France, on nous permettra de relever le résultat des observations dues à M. Chapelon Coulvier Gravier.

Ce laborieux observateur a constaté que malgré le mauvais temps qui a accompagné à Paris les nuits des 8, 9 et 10 août, quelques éclaircies indiquant déjà l'arrivée prob.ble d'une pluie météorique importante ont été aperçues dans cette période.

Ces précieuses se sont trouvées réalisées. En effet, l'observation faite pendant la nuit du 11 au 12, par un ciel parfaitement serein, donnait un nombre horaire moyen de 111 étoiles ramené à minuit.

Ce nombre, en tenant compte des moyennes précédentes, a été ramené à 138, à pour le maximum, ce qui donne une augmentation de 28, 1 sur le maximum de 1848, le plus remarquable du siècle.

Comme toujours, les centres d'émanations visibles à cette époque se trouvaient près du zénith et par conséquent dans les constellations de Céphée ou de Persée.

Faut-il rappeler que le grand Arago, dont on va bruyamment inaugurer la statue à grand orchestre à Perpignan, est un des premiers astronomes qui aient observé les étoiles filantes; que c'est grâce à sa protection que M. Coulvier a pu se livrer à la recherche des astres; que notamment, lors de la rédaction des instructions destinées aux officiers de la *Bonite*, il mit les observations des étoiles filantes au premier rang de celles que l'on devait faire; qu'il ne négligeait jamais de faire observer ces étoiles filantes à l'Observatoire dont il était le directeur, ni de communiquer le résultat de ces observations à l'Académie des Sciences dont il était le secrétaire perpétuel.

Nous avons honte de nous étendre plus longuement sur un sujet si triste, si douloureux pour notre amour-propre national.

Nous devons ajouter cependant que l'échéance de nov.mbre offre un intérêt part.culier, surtout pendant la nuit du 27, jour où l'on peut espérer retrouver les débris de la fragile comète de Biela.

C'est M. Newton de Yale Haven qui nous a communiqué lui-même à Sheffield ce renseignement.

Il a fait de même aux astronomes anglais qui ont pris la résolution d'organiser une série d'observations non-seulement en novembre, comme les années précédentes, mais pendant les nuits aux lune de septembre et d'octobre, en balayant certaines régions du ciel que M. Newton leur a indiquées, et où les débris de la comète, quoique encore éloignés de la terre, peuvent se trouver si elle n'a pas été réduite en poussière et complétement désagrégée.

Ces recherches sont exécutées, aussi en France, dans tous les pays civilisés.

Elles intéressent les électriciens d'une façon tout à fait directe, car il est possible que l'approche d'un courant météorique influe sur les éléments magnétiques du globe et produise même à la surface des régions voisines du point de rencontre des courants spontanés.

54

OBSERVATIONS EXPÉRIMENTALES

Sur les effets mécaniques qui accompagnent les décharges électriques

En 1811, M. Abria, professeur de physique à la Faculté des Sciences de Bordeaux, eut l'idée fort ingénieuse d'employer à l'étude des phénomènes mécaniques qui accompagnent les décharges un procédé analogue à celui dont se servit Chladni pour l'étude des surfaces nodales.

Le savant physicien disposa l'excitateur universel de manière à faire passer entre les deux pointes placées sur une ligne horizontale, la décharge soit d'une bouteille de Leyde, soit d'une batterie quelconque.

A 20 centimètres au-dessous de la ligne des pointes, il plaça une plaque sur laquelle il avait répandu aussi également que possible, à l'aide d'un tamis à mailles très-serrées, de la craie finement pulvérisée.

Après quelques décharges, si l'on n'a pas mis trop de poussière, on trouve que les particules de craie offrent une forme parfaitement régulière.

Non content d'indiquer ce beau phénomène, M. Abria en donna l'explication complète. Il montra que ces accumulations de poussière sont dues à la dilatation de l'air qui s'échauffe lors de la neutralisation des fluides, et au mouvement contraire qui le fait ensuite fair remplir le vide produit dans les premiers instants par la chaleur corrélative de l'apparition de l'étincelle.

Les conditions de l'expérience ont été variées de mille manières différentes, en modifiant la distance des pointes et celle de la plaque, ainsi que la masse électricité en mouvement.

En général, les lignes tracées par la poussière sont des portions d'ellipse régulièrement orientées.

Si on remplace des boules par des pointes, l'action mécanique semble se propager à une distance plus grande.

On peut encore placer les pointes sur une même verticale et percer la plaque d'un trou central, et le cuivre, ou mettre les poussières sur une plaque de métal.

Dans ce cas, les lignes semblent appartenir à des arcs de cercle.

L'expérience réussit bien et n'offre que des différences secondaires, quelle que soit la nature de la plaque ou de la matière pulvérisée, pourvu qu'il n'y ait point d'humidité et qu'aucune adhésion ne retienne les particules de matière.

On peut reproduire ces phénomènes dans l'air raréfié, mais l'interval des lignes augmente à mesure que la pression de l'air diminue. On peut également opérer dans l'hydrogène et dans l'acide carbonique.

M. Abria s'est également préoccupé du soin de constater que l'électricité n'entre ici que comme un agent de combustion rapide.

Si, après avoir répandu de la poussière sur un plan de marbre, on forme des lutles semi-sphériques d'un mélange détonant, l'inflammati on chasse les particules qui recouvraient un espace plus ou moins étendu.

Mais au delà de la surface balayée, on voit reparaître des lignes près n anat les mêmes apparences que celles qui ont été produites par les décharges électriques.

On peut obtenir le même résultat avec le fulminate de mercure; cependant les lignes sont moins distinctes qu'avec les hémisphères d'eau de savon remplies de mélange détonant.

Ces recherches viennent d'être reprises par MM. Schellbach et Buchn, qui ont eu l'idée de les varier, de manière à obtenir des figures véritablement analogues à celles que l'on montre dans les cours d'acoustique.

Si on place à droite et à gauche de l'excitateur deux plans divergeals à la surface desquels les ondes d'ébranlement puissent se réfléchir, on obtient des ondulations renfermées dans l'angle de ces deux lignes.

En faisant varier la nature et la position des surfaces réfléchis antes, on pourrait obtenir une multitude de formes variées très-curieuses, mais trop compliquées pour que la description puisse être suivie avec fruit.

Les auteurs on ont tiré aur l'acoustique des déductions dans lesquelles nous ne les suivrons point.

Nous nous bornerons à faire remarquer que M. Abria et ses deux imitateurs vont peut-être un peu loin en excluant toute idée d'une action électrique proprement dite. Quelques anciennes expériences de Faraday, sur lesquelles nous aurons occasion de revenir, semblent précisément indiquer le contraire.

55

Transmitting Voice by Telegraph.

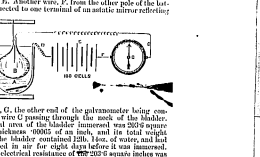
Dr. H. P. Lieke, of the Smith Institute, D., after three years' labor, has succeeded in his perfected an instrument by which forms and colors can be sent by wire the same as words are sent. He calls the instrument a diaphota. The word diaphota, from the Greek, dia signifying through and photos signifying light, has been selected as its name, implying that the light traveled through or along a wire. He read a paper on his invention before a scientific society.

The diaphota consists of four essential parts, the receiving mirror, the transmitting wires, a common galvanic battery and the reproducing speculum. The Doctor gave a detailed account of the many experiments undertaken to determine the proper composition and arrangement of the mirror and speculum. In the diaphota exhibited, the mirror was 6 inches by 4, and had 72 fine wires, which were gathered together in one about a foot back of the frame, the several being finely wrapped with an insulated thread. The corresponding receiving speculum each little wire connected to a division similarly placed as in the mirror. From a common galvanic battery wires run to the diaphota, and thus a circuit was formed which could be closed or not at pleasure. The theoretical action of the instrument appears now to be the following: The waves of light from an object are collected through the ordinary camera, so that they fall on certain of the divisions of the mirror when the electric circuit is closed. The light and corresponding heat produces momentary chemical changes in the amalgam of the mirror—which consists of a peculiar compound of selenium and chromium. These changes modify the electric current and cause similar changes in the corresponding portitions of the remote speculum, thus reproducing a similar image, which, by a second camera, may be readily seen by the eye or thrown upon a screen. Dr. Lieke explained how the proportions of selenium in the mirror and speculum were obtained by scientifically adjusted to the size of the divisions and the resistance of the electric circuit, so that the light which struck any portion of the reproduced image, that, he said, had been the problem which had caused him the most difficulty, and which at one time had seemed almost insurmountable.

All the rays of the paper on illustration was given of the powers of the instrument. The mirror of the diaphota, in charge of a committee of three, was taken to a room in the lower part of the building and the connecting wires laid through the halls and stairways to the speculum on the lecturer's platform. Before the mirror the committee held, in succession, various objects, illuminated each by the light of a burning magnesium wire, and simultaneously on the speculum appeared the secondary images, which for exhibition to the audience were thrown on a screen, considerably magnified. An apple, a pocketknife and a trade dollar were the first objects shown; in the latter the outlines of the goddess of Liberty were recognized, and the words "In God We Trust" were legible. A watch was held directly before the mirror, and the audience could plainly perceive the motion of the minute hand on the screen, but the movement of the second hand was not satisfactory and, although Prof. Kamich, by looking into the camera, thought that it was there quite perceptible, An ink bottle, a flower and a part of a theater handbill were also shown, and when the head of a little kitten appeared on the screen, the club testified its satisfaction by the most hearty applause. After the close of the experiments the scientists attended their congratulations to Dr. Lieke, and the President made a few remarks on the probable scientific and industrial applications of the diaphota in the future. With the telephone and the diaphota it might yet be possible for friends, separated by the wide Atlantic, to hear and see each other at the same time; to talk, as it were, face to face.

HARDENING ELECTRODES.—Mr. W. H. Barlow, the new President of the Institution of Civil Engineers, London, in his recent inaugural address, speaking of the rapid growth of telegraphy and other practical applications of electricity, said that the diminution of power, from increased length of the conducting wire, had been surmounted by relays of power at fixed stations. (This was the discovery of Morse.) By employing this ingenious expedient on the Indo-European Telegraph, Calcutta had frequently been put in direct communication with London, a distance of 5,000 miles. He further stated that Mr. Siemens had ascertained that in employing electricity for the transmission of power, including all sources of loss, one-half of the original power could be realized by electric wires at a distance of one mile from the motor; and that with adequate provisions against hostility it would be no dearer to transmit electro-motive power to a greater than to a smaller distance. Sir William Armstrong, by means of an electro-ballistic arm wire, wrote in circular saw at a distance of a mile from the water wheel that turns the electric machine. By the same means Dr. Werner Siemens works a locomotive that carries thirty persons.

At the last meeting of the Society of Telegraph Engineers, during the discussion of Dr. Gladstone's paper on "Induction in Parallel Circuits," Mr. Willoughby Smith described a very interesting experiment he had made with the Gutta Percha Company's gutta percha, which well illustrated the electrical character of that material. In an inverted glass shade, A, containing clear water, was suspended a blacker of gutta percha, B, filled with water; through the neck of the blacker was a copper wire, C, which was in contact with the water in the blacker. A copper plate, H, was immersed in the water in the glass vessel, and a wire, D, connected with it was attached to one pole of 100 Menotti battery cells, E. Another wire, F, from the other pole of the battery was connected to one terminal of an astatic mirror reflecting



galvanometer, G, the other end of the galvanometer being connected to the wire C passing through the neck of the blacker. The superficial area of the blacker immersed was 2826 square inches, its thickness .0005 of an inch, and its total weight 32 grains. The blacker contained 22lb. 14oz. of water, and had been suspended in air for eight days before it was immersed. The absolute electrical resistance of the 2826 square inches was 1.487 megohms at the end of one minute's electrification, and of ten minutes it was 41078 megohms. The absolute electrostatic capacity was .2290 microfarads. Its behaviour during the test was precisely the same as that of copper conductors and similar gutta percha for telegraphic purposes when similarly placed. Mr. Smith is continuing the experiments with the view of determining a true unit for the electrical capacity of gutta percha.

THE TELEPHONE AIDED AS INTERPRETER.—A correspondent sends us a Swansea paper, containing an account of how dent sends us a Swansea paper, containing an account of how an interesting entertainment came by telephone. It seems that the agent at the Swansea having undertaken to erect a telephone line for the Corporation advertised for poles. A Welshman, with poles to sell, called to strike a bargain, but on attempting business it was found that the Welshman knew nothing of English, and the agent nothing of Welsh. The common word was "telephone." The agent thought for a moment, and then walking to a telephone called to a friend at the other end of the line, who could understand Welsh. His friend conversed with the Welshman, translated the conversation to the agent, facilitated business, and made that plain which seemed so difficult

PHOSPHORESCENCE PRODUCED BY ELECTRICAL DISCHARGES.—Most of the phthalocyanides, according to the abstract of a paper by E. Wiedemann on this subject, in the *Chem. Soc. Jol.*, exhibit fluorescence under the influence of electrical discharges, but the fluorescence is dichroic only as the result of a partial decomposition. Dichroism is induced in barium platino-cyanide without any electrical action by placing the salt in a vacuum for a time. The author attributes this effect to the loss of water, by which loss the optical differences of the several directions in the crystals are more strongly brought out. That dichroism is so much more quickly developed in the salt when it is subjected to electrical discharges, he explains by the warming of the crystals by the discharge. The superficial parts of the crystals thus losing their water become dichroic, whilst the deeper-lying parts fluoresce under the influence of the electric discharge. These experiments were suggested by a research of Crookes's, from whose view of the cause of the phenomena, however, the author dissents. Instead of a stream of projected molecules, we have here, the author contends, to do with electrical disturbances or waves, communicating their motion to either of the solids in which vibrations are thus set up, that appear partly as heat, partly as light. A striking proof of the incorrectness of Crookes's theory is an experiment in which the positive current of a Holtz machine is passed through a discharged tube, made with thick glass, in such a manner that it may be diverted within the tube by the finger. A feeble phosphorescence then appears in the inside of the tube, but on the outside a very bright green light is seen. Closely connected with this phenomenon is that which appears when a spherical positive electrode is used within a glass globe, and a collecting point touches the external surface of the globe. On the opposite part of the globe is seen a well-defined shadow of the electrode, surrounded by a circle of beautiful green rays. The starting point for a theory of these phenomena is supplied in Maxwell's equations ("Wied. Galv.," p. 1230). An electrical discharge effected by the motion of material particles is out of the question, as the velocity of electricity in gases is immensely greater than that of any molecular motion whatever. The reflection of the negative discharge from surfaces on which it impinges is likewise in accordance with Maxwell's theory, if we attribute to the waves of electric polarisation sufficient energy; and that they do in fact possess this may be inferred from their melting the glass upon which they strike.

Electrician Sept 17 1880

Mineral Veins and the Electric Current

The Grass Valley *Union* of October 25th says:

"Mr. Phillips, who claims for his electric machine the merit of indicating the course of mineral-bearing veins, and their relative size and character, has lately been experimenting upon the Idaho Hill mine, below Rough and Ready. He found the shaft to have been sunk upon a stringer of good size, but not upon the main ledge. The instrument indicated the lay of the main ledge, which was some distance from the stringer, and from following this indication the main ledge has been found, carrying out strongly in a series, where it had not before been discovered, and showing a width of from ten to twelve feet. Miners generally do not place faith in the discovery of ledges by such means, but Mr. Phillips has unlimited faith in the efficacy of the machine, claiming that it is just as practicable to use electricity in discovering the existence and course of blind ledges as mineral is above ground or under water in transmitting telegraphic intelligence. Prof. Edison, we believe, advanced similar ideas when he visited the Comstock. The possibilities of science are very great, and experience will yet demonstrate whether this is one of them."

We give the above to illustrate the modern tendency of science to experiment upon old ideas with recent mechanical appliances.

Fifty years ago (in 1830), the relation between metallic veins and the electric current was discussed in the *Institut de France* (*séance du 12 Octobre*), and it was announced that William Fox, from observations made in the mines of Cornwall, had discovered that their veins exerted a manifest action upon the magnetic needle. *The direction of the currents being in general with the inclination of the vein, and the axis of the magnetic poles.* "*La direction des courants était en rapport avec l'inclination des filons et avec l'axe des deux magnétiques.*"

Becquerel, in his *Traité de la Commagnetie et de la Terrestre*," in 1834, upon the subject of the formation of metallic veins (page 240), says: "I attribute them (the veins) to the action of the telluric and even hydro-electric currents which traverse the terrestrial beds, and these incessantly deposit or modify certain metallic substances. Basing this hypothesis upon the belief that the earth is similar to a galvanic battery which transports elementary molecules in the same manner as the Voltaic pile.

"*Nous les attribuons a l'action des courants telluriques et meme, hydrogen, tres, lesquels les courants terrestres, y déposent ou y modifient, incessamment certaines substances metalliques.* " *Nous et transportant des molecules élementaires absolument comme les courants de la pile Voltaique.*"

We might cite many other instances of the connection between metalliferous veins and the electric current, but we have said enough to show that the idea is not new. Perhaps if the same amount of investigation were bestowed upon this theory of the formation of mineral veins, more might be accomplished than through other speculations.

Curious Electric Phenomenon

At about [illegible] with a deluge of rain came up from the South-west and lasted about an hour. At 5.30 my wife was standing at the window watching the receding storm, which still raged in the south, just over Leicester, when she observed, immediately over a double flash of lightning, what seemed like a fallen star, or a firelock from a rocket, drop out of the black cloud almost above the horizon, and descend perpendicularly till lost behind a belt of trees. The same phenomenon was repeated at least a dozen times in about fifteen minutes, the lightning flashes following each other very rapidly and the thunder consisting of short and sharp reports. After nearly every flash a firelock descended. These balls appeared to be about one-fifth or one-sixth the diameter of the full moon, blunt and rounded at the bottom, and seen not into a tail above, and leaving a train of light behind them. The colour was nearly white, but one was distinctly pink, and the course of one was sharply zig-zagged. They fell at a rate certainly not greater than that of an ordinary shooting star. I have never witnessed a phenomenon of this kind myself, but my wife is a good observer, and I can vouch for the trustworthiness of her report.

Nature August 19 1880

THE AURORA Nature

OUR experiments on the electric discharge, which have been already published in the *Philosophical Transactions* and the *Proceedings of the Royal Society*, enable us to state with some degree of probability the height of the aurora when it exhibits its display in of maximum brilliancy, and also the height at which this phenomenon could not occur on account of the great tensity of the atmosphere.

In Part III., of our electric researches, *Phil. Trans.*, Part I. vol. 171, we have shown that the least resistance to the discharge in hydrogen is at a pressure of 0·52 millim., 684 M.; after this degree of exhaustion has been reached a further reduction of pressure rapidly increases the resistance. When the exhaustion has reached 0·002 millim., 3·26, the discharge only just passes with a potential of 1,000 chloride of silver cells (15,330 volts); at the highest exhaustion we have been able to obtain (real which we believe has not been surpassed), namely, 0·000003 millim., 0·005 M., not only did 11,000 cells fail to produce a discharge, but even a 1-inch spark from an induction coil could not do so.

Although we have not experimentally determined the pressure of least resistance for air, we have ascertained that while the discharge occurs in hydrogen at atmospheric pressure between disks 0·22 inch distant, they require to be approached to 0·13 inch to allow the discharge to take place in air. We may therefore assume that the pressure of least resistance for air is

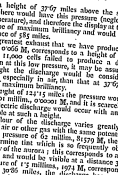
$$\frac{0{\cdot}52 \times 13}{22} = 0{\cdot}379 \text{ millim., } 498 \text{ M.}$$

At a height of 37·67 miles above the sea level, the atmosphere would have this pressure (neglecting change of temperature), and therefore the display at this elevation would be of maximum brilliancy and would be visible at a distance of 585 miles.

The greatest exhaust that we have produced, 0·000005 millim., 0·006 M., corresponds to a height of 51·27 miles, and as 11,000 cells failed to produce a discharge in hydrogen at this low pressure, it may be assumed that at this height the discharge would be considerably less brilliant, especially in red, than that at 37·67 miles, the height of maximum brilliancy.

At a height of 12·15 miles the pressure would be only 0·00000001 millim., 0·00001 M, and it is scarcely probable that an electric discharge would occur with any potential conceivable at such a height.

The colour of the discharge varies greatly with the tensity of air or other gas with the same potential. Thus in air at a pressure of 62 millim., 81·270 M, the discharge has the carmine tint which is so frequently observed in the display of the aurora; this corresponds to an altitude 12·4 miles, and would be visible at a distance 336 miles. At a pressure of 1·5 millim., 1·974 M, corresponding to a height of 30·65 miles, the discharge becomes salmon-coloured, having completely lost the carmine tint. At a pressure of 0·8 millim., corresponding to 33·96 miles, the tint of the discharge is of a paler salmon colour, and as the exhaust is carried further it becomes a pale milky white. The rescarce and salmon-coloured tints are always in the vicinity of the positive source of the electric current, the positive luminosity fades away gradually, and frequently becomes almost invisible at some distance from its source; in this instance, in the hydrogen discharge accompanying figure, *II*, which resembles in some



respects the phenomenon of the aurora. The discharge at the negative terminal in air is always of a violet hue, and this tint in the aurora indicates a proximity to the negative source.

The following table, [illegible] with the exception of pressure

[illegible]

[illegible]

[illegible]

having a small orifice in its bottom, to one of the terminals of the circuit, and a shallow metallic basin to the other. The vessel, being now filled with acidulated water, is held over the basin, so that the column of water from the orifice does not break, and so completes the electric circuit. By gradually raising or lowering the upper vessel, a longer or shorter column of liquid can be made part of the circuit. On listening in the telephone, so long as the liquid vein is short and limpid, no sound whatever is heard. This shows that the electric current has uninterrupted circulation. On gradually lengthening the liquid vein, a point is reached when a rattling noise is heard in the telephone. This arises from the slowest resistance current in the liquid vein beginning to break up into globulea. On still further lengthening the vein, a point is very soon reached when all sound in the telephone again ceases. This corresponds to the stage when the liquid vein has actually separated into detached drops, and so broken entirely the electric circuit.—*Proceedings of the Royal Society of Edinburgh.*

NOTE ON SOME EFFECTS PRODUCED BY THE IMMERSION OF STEEL AND IRON WIRES IN ACIDULATED WATER.

BY PROF. D. E. HUGHES.

During a discussion upon a very interesting Paper by our President, "On the Durability of some Iron Wire," I mentioned a fact which I had lately observed, viz., that steel or iron wires immersed for a few minutes in acidulated water, containing 1-th sulphuric acid became excessively brittle. Upon repetition of these experiments, I have found that this brittleness is no mere result, due to some fine flaw in the steel or iron wires, but that the resulting brittleness is invariable in all kinds of steel as sulphuric acid to the water may be, in fact, so we shall see later, to any particular acid. The effects, however, seem confined to steel and iron, as by similar treatment I have as yet obtained no perceptible effect on copper or platinum. Mr. W. Chandler Roberts predicted that the effects were probably due to the absorption of hydrogen. I have tested these wires in various ways since then, but can find no change whatever in its magnetic conductivity, the conditions of the experiments are such as to favour the absorption of hydrogen. Using two steel wires as electrodes in sulphuric acid and water, we find that both wires have become brittle, though in a very different degree, the wire connected with the zinc or negative pole remaining bright, although excessively brittle, whilst the one connected with positive pole is much corroded, and but feebly brittle, with this arrangement. I believe that these effects are due to the absorption of hydrogen when the hydrogen is in the "nascent" state. Hydrogen seems to permeate through the entire mass, for iron rods 1 inch thick were equally affected, requiring more time, or, in other words, a supply of nascent hydrogen sufficient for the larger mass; and once the wire has become hydrogenised (if we may be allowed the expression), it retains it under all circumstances of time and change of surrounding atmosphere. Heat alone of all the means I have tried has any effect, and if we heat a wire to cherry red in a spirit lamp, we find that it is completely restored to its primitive flexibility in a few seconds. These effects may be obtained sulphuric acid and water of any proportion, say $\frac{1}{10}$th, becomes more electro-negative than at the first instant of plunging. If we take amalgamated zinc as the positive element, and a steel or iron rod or wire for negative, we find that there is such a remarkable similarity of electromotive force between all kinds of steel and iron that we are forced to the conclusion that we are simply testing the electro-negative qualities of hydrogenised iron, the force being with amalgamated zinc 58. I remarked here a remarkable fact, and which does not agree with the results of many authorities. I found that as soon as the iron rod had absorbed its maximum of hydrogen (a few minutes after being short-circuited) that it became a constant cell, giving but small traces of polarisation then or after being short-circuited for hours at a time. There occurs, however, a slight diminution of electromotive force after a few days' hard work, being then 52, due to the acidulated water becoming neutral by the formation of sulphate of zinc and iron. If, however, we wish to restore its full electromotive force, we have only to short-circuit the cell for a few seconds, torrents of hydrogen will be given off, and its electromotive force becomes, on testing at its highest value, 58. If we short-circuit the hydrogenised iron cell for one minute, and at once test its electromotive force, we shall find at the first instant a certain amount of polarisation, about 10 per cent, but it rapidly recovers, being at its full initial force in ten seconds' time, or after a few minutes' short-circuit even sooner. Iron or steel wires thus hydrogenised, and then exposed to the air, lose their hydrogen, and become brittle, and may be thus deprived of their hydrogen in a few seconds by heating in the flame of a spirit lamp. Hydrogenised steel wires, when heated in a glass tube, evolve hydrogen, and become brittle

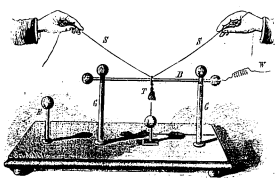
EXPERIMENT ILLUSTRATING DISCHARGE OF ELECTRICITY FROM CLOUDS.

Mr. Lomax gives the following easily performed experiment in the *Colliery Guardian*. It illustrates some of the phenomena of thunderstorms:

In the engraving, A is the base of the instrument, made of wood and brass. G G are glass legs supporting an arm of brass, B. The cloud is here represented by the moving tassel, T, pulled backwards and forwards by the strings of silk, S S. O is a ball provided with a point or lightning conductor. This ball is not insulated, that is, not supported by a glass leg. W is a wire leading to an electrical machine. On working the machine electricity is spread over the arm, B. The tassel consequently diverges, owing to each filament being charged with like electricity. On drawing the tassel (cloud) over the lightning conductor, O, an opposite kind is given off at the point and neutralizes the cloud and the hairs or fibers collapse. If we were to wholly detach the tassel and work the machine till we raised a large envelope of electricity around the arm, B, a vivid flash of light (lightning) would pass to uninsulated conductor, R. If the ball, O, was not provided with a point, on moving the electrified tassel along the arm, B, it would not collapse on passing the ball, except that a faint spark was given off. If this spark took place, you have what often happens in nature.

Persons ought never to stand near a tree nor a house, nor even a building provided with lightning conductors, for shelter. My reasons are these: Wood is a poor conductor, masonry worse, and if buildings provided with these conductors are not what they ought to be, they only invite destruction.



ILLUSTRATING DISCHARGE OF ELECTRICITY FROM CLOUDS.

64

ELECTRIC DISCHARGES THROUGH GASES.—In a recent valuable paper on the thermal and optical behaviour of gases under the influence of electric discharges, Herr E. Wiedemann first studies the thermal phenomena in the case of discharges of the influence-machine, and indicates a different behaviour of the positive and negative electricity. He then describes an experimental attempt at a special determination of the quantities which produce a change of the bands of spectrum of hydrogen into the line-spectrum. He further investigates the nature of the discharge from the negative electrode in greatly rarefied space. Then he discusses the applicability of other electrical sources, inductoria, large galvanic batteries, and Leyden jars, to spectrum-analytical researches, also the continuous and discontinuous discharges in gases. The paper concludes with theoretical considerations as to the phenomenon of discharge in gases and the nature of spectra.—*Nature*.

THE YELLOW LIGHT.

AN INTERESTING STUDY OF COLOR AS AFFECTED BY THE ATMOSPHERICAL PHENOMENA OF TUESDAY LAST.

To the Editors of the Boston Daily Advertiser:

So emphatic a lesson in color as the yellow light of Tuesday is rare enough to justify special notice from that point of view, though we have similar lessons, but of such fine gradations that probably not two artists would agree in naming the same definition. But fortunately every one noted the prominent transformations. To every one the gas lights were whiter than the daylight, and to us called the electric light to every mind. The startling hues of grass, trees, and flowers were an amazement even to the most astute. It differed from a London fog in its purity of color and consequent hope in the strange changes it produced.

To believe these changes intelligently we need but keep in view that the yellow light on an eye used in the nature medium neutralizes yellow in all colors which contain it, and adds it to the others; thus sunflowers seemed bleached, and those on the line, while keeping a value of white, came near to it. The yellow being eliminated from the grass and leaves left them as nearly a pure green as we can ever have them, and the pinks, or any of that series of hue, through a long scale of amount of reserve, were robbed of their yellow, and became very exalted ones. Violets became more violet, gold were tarnished with gold, while the purple, the blue, the green, the rose, the yellow lilac, and the blue of the plants under a reddening rack effect to a white and startling degree of unreality.

I had no expectation of observing a genuine blue but am confident it would have appeared either green or violet, probably the latter. Every eye, of trained color, would simply have observed the absence of yellow, though from different causes. The green would have been intensified both by the elimination of yellow in the sun, and by the contrast of green, which in its turn would have made the violet more so. In the case of neutral tones, such as ashes of rose, or lilac, become various hues of orange and red, and the neutral grays changed entirely from contrast. The pure green particularly, and to fortunately contrast, all varied unreal, and the effect of the whole was to give to the eye, bathed in the light or so illumined in all reflections as to pass into its tones. The distresses as to color in the dress of ladies were many, perhaps owing to the newness of the light and the unreal influences of the local color. A fame more white in the face than the light, or a cheek more rosy, a more disturbed bottom would be looked for. It is further worthy of note that gold ornaments, even when not yellow, were blanched in appearance, but rather lustered.

Later the light deepened to a copper color, in which trees seemed genuinely tragic to behold, and shortly the yellow and red were withdrawn, and the green, violet, and blue were left to their nature, not agreeable, but more akin to usual experience. Indoors, with gas flames white and steady, the effect was not so striking, though possessing a sense of gold, the characteristic of these lines were as strange as those without. I note that the effect of the yellow light destroys the wonderful purity of a blanch of white flowers was a thing of which I never saw the like.

Of the yellow light, high fog with light smoke behind it was a striking feature among the vari-colored appearances. The fog seemed the vari-colored appearances. The fog seemed the vari-colored appearances. The fog seemed

ESSAYS IN SCIENCE.

(CONTINUED FROM FIRST PAGE.)

Please we must be content with one remarkable case. Judge Hazeltine's work will be published in the forthcoming instalment.

SELENIUM AND THE PHOTOPHONE.

Alexander Graham Bell upon the Production of Sound by Light.—Researches by Professor Tainter and the Inventor of the Telephone.—A New Discovery.

In bringing before you some discoveries made by Mr. Sumner Tainter and myself, which have resulted in the combination of apparatus for the production and reproduction of sound by means of light, it is necessary to explain the state of knowledge which furnishes the starting point of our experiments. I shall first describe the remarkable resistance selenium, also the analogous, almost identical property exhibited by sulphur, and the final result of our researches has evidenced the class of substances capable of light-telephony, until we can pronounce the fact of such sensitiveness being a property of all matter. We have found this property in silver, platinum, iron, steel, brass, copper, zinc, lead, antimony, German silver, Jordan's metal, Babbitt's metal, ivory, reindeer, gutta percha, hard rubber, slate, marble, coal, colored paper, parchment, wood, mica and all vegetable substances, as well as in the ordinary vulcanized rubber,

and reservoirs. The *Fundamental Idea*, on the formation of crystalline structure, the *Principle of Variation in Crystalline Form*, the *Principle of Variation in Crystalline Form by Light*, the *Principle of Variation in Crystalline Form by Electricity*, etc., etc.

During the winter of 1875-7 I never knew that I was consciously using the selenium cell, but it subsequently appeared that upon that occasion I was subject to rapid changes, in temperature, occasionally amounting to 10 degrees, in the course of a minute of a second or of two minutes the temperature. The cell was suddenly brought into a room where the temperature was 70° F., and I was in that room myself. The experiment was performed in the presence of Professor Tyndall, of the Royal Institution, and of Professor Abel, of Woolwich, but to this day I have not been able to discover the reason why the selenium cell refused to act. I did not then know that the selenium cell was extremely sensitive to changes of temperature, and that the action of light upon it was greatly increased by the presence of moisture. The cell was subsequently

Electric Storms.

Professor Tait explains the formation of the whirlwinds which occasionally sweep the Western America. Sixty are electrical storms, not wind storms. There was no wind attending a recent tornado at Marshfield. Among the evidence of the electrical nature of that storm he notes the fact that it destroyed every building which had a tin roof, or which had metal of any kind in its roof. In Marshfield it passed directly over several buildings with shingle roofs, and tore to fragments others, not more exposed, which had metal roofs. A mill situated over a quarter of a mile away from the centre of the cyclone, had its iron chimney torn out and carried a long distance, while the mill itself suffered very little damage. The cupola of the public school building at Marshfield, which had a tin roof, was wrecked, but the building, which was roofed with shingles, was not injured to any extent. Even more constructive and remarkable, he thinks, were the phenomena manifested in connexion with trees and shrubs. The bark was stripped from the trees and bushes, not alone on those sides exposed to the force of the cyclone, but on all sides. The ends of the branches were not only denuded of their leaves and bark, but were rifled into fine fibres, so that they presented the appearance of little brooms. The active agent in such cases, he insists, was not wind, but electricity. Under its influence the sap under the bark was instantly converted into vapour or gas, expanding 2000 times in volume, and as by an explosion, tore off the bark, shattered the trunk, and split the green twigs into fibres.

JAS. CROLL, F. R. S., makes mention of an article written by himself in *Phil. Mag.*, xxxii., 1866, pp. 213-216, which may not have been before presented to American public, in which he conjectured the annual fall of frost observed between a black-bulb thermometer exposed to the direct rays of the sun, and one shaded, *downwards*, to a second into the atmosphere. Mr. Croll deduces from this that radiation into stellar space is the medium for the production of snow in elevated places, and the protective action of aqueous vapor the cause of its melting in places where there is a greater snowfall, a remark in perfect harmony with Prof. Tyndall's important discovery regarding the influence of aqueous vapor on radiant heat.

AN ELECTRO-DYNAMIC PARADOX.

Dynamo-electric machines, like M. Gramme's *Alternate current* and can either generate a current from mechanical work, or, from continuous current magneto-electric machines do the same thing. But if the current from a dynamo-electric machine is sent into a magneto-electric machine, a very strange effect results. This effect is signalled by M. Gérard-Lescuyer, who calls it an electro-dynamic paradox.

Soon as the circuit is closed the magneto-electric machine begins to move, and tends to acquire a speed proportional to the intensity of the current actuating it. But suddenly its slackens speed, stops, and then begins to rotate in the contrary direction, only to arrest itself anew and begin again as before. In a word, it exhibits a regular alternative motion, lasting as long as the current which actuates it.

What, asks M. Lescuyer, is the cause of this phenomenon? Evidently the motive current changes its direction; and a galvanometer introduced into the circuit proves it. But how does it produce itself when the speed of the prime mover, be it steam or other engine, does not vary? The effect must be due to an exterior cause reversing the polarity of the inductors of the dynamo-electric generator so as to cause it to give birth to a reversed current. This reversal is proved by placing a compass near the inductors, and this reversal keeps time with the reversal of the current, as shown by the galvanometer in circuit with the machines.

Let us suppose that the magneto-electric receiver has periodic increases of velocity. These will give rise to a current of its own in the magneto-electric machine, which will traverse the dynamo-electric machine, and, as it will be a contrary current to that coming from the latter, it will tend to reverse the polarity of the inductors of the dynamo-machine. Hence a reverse current will proceed from the latter.

To test this hypothesis it is sufficient to prevent the increase of velocity in the magneto-electric receiver by means of a brake. As soon as the brake is put in play the paradoxical effect vanishes, and the receiver goes uniformly in the same direction, whilst the galvanometer and compass are unaffected. The experiment is well shown by a Siemens dynamo-electric continuous current machine for generator, and a small laboratory Gramme with ordinary permanent magnets, as constructed by M. Breguet, for receiver.

EARTH CURRENTS.

St. Leonards, Aug. 1, 1880

Several communications have appeared in our daily contemporaries, referring to aurora, seen by various observers on August 12th. In "Nature" will be found those inserted in *The Times*. Connected possibly with this phenomenon we have accounts of strong earth currents on and about this date. A most interesting statement describing the earth currents on various cable lines, has been sent to us by Mr. H. Sumner, electrician in chief to the Eastern Telegraph Company. The phenomena of earth currents are so universal, so important to science, and so little understood, that we hope some way will be found to accumulate facts from which data may possibly be deduced. Mr. Saunders, speaking of the electrical and magnetic disturbances of the 12th and 13th August says —

"The earth currents on those days were exceptionally strong and variable, causing great interruption to the traffic over all the English and Continental lines, so much so that the Director of Telegraphs in France gave notice in the papers of the cause of delay to telegrams.

"I have collected the following data as to what was observed on the Eastern Telegraph Company's system and the Eastern and South African Company.

"Between London and Porthcurno, and London and Marseilles and London and Liverpool, there were very considerable disturbances all day of the 12th, the maximum effects being observed between 11 a.m. and 4 p.m.

"The English Government and the Submarine Company's systems were also affected.

"The system upon which we work most of our lines, which is purposely intended to block earth-current disturbances, prevents them being noticed except when very strong and variable, so that on the cables from Porthcurno to Lisbon and Vigo nothing very unusual was observed; but upon a cable from Lisbon to Vigo, which is undergoing repair, and upon which an instrument is kept in circuit, strong and variable currents were observed on the 12th and 13th, the maximum being between 11 a.m. and noon, the weather being unusually calm and the sky thickly overcast.

"At Gibraltar very strong currents were observed on the cable to Lisbon at 10.25 a.m. of the 12th and the 12th being the strongest both on the Lisbon and Villa Real cable, maximum at 11.46 a.m., and currents on both cables during the 13th, but not so strong. Little or no current was noticed on the cable between Gibraltar and Malta on either of the days.

"Malta observed nothing unusual on the cables connected with Gibraltar, Marseilles, and Alexandria, nor did Alexandria observe anything on any of the cables connecting Malta, Cyprus, and Candia. In the Levant there was considerable disturbance on most of the lines. The Otranto Zante cable was violently disturbed between 10 a.m. and 4 p.m. the 12th, and the Zante-Candia line the whole of the day, rendering working very difficult.

"On the 13th the former section was free, but the latter still slightly disturbed. Candia did not have anything unusual either on the Syra or Alexandria cables. The Syra-Candia line was very strong. The cables connecting Syra with Pentedeo, and Pora and Tenedos and Salonica, as also on the Turkish lines, both on the 12th and 13th. The currents were not observed on the cable at Cyprus connected with Alexandria, but were on the land lines on both days, strongest on the 13th, and on the Larnaca-Limassol section. Nothing exceptional was observed on the cables between Suez, Aden, and Bombay. African cables between Zanzibar, Mozambique, Delagoa Bay, and Natal. It is all the more curious that, as a rule, these lines are very free from earth currents.

"This is, of course, very imperfect record, owing to the fact that cables are direct-reading machines in the first place, so that when there is trouble on the lines the first thing we do is to get the staff are deadred to getting the traffic through, and have little time for accurate recording.

"However, the salient points are sufficiently determined, viz. —

1st. The extent of the disturbance extending over Europe, as far as Constantinople, down to the extreme points of the southern coast of Spain, and also over the extreme points of the northern near the Red Sea, but turning up again at Zanzibar and along the east coast of Africa.

2nd. The remarkable coincidence as to the time of maximum effect at different places being separated.

"These disturbances are generally accompanied by displays of the aurora borealis, and I see from a letter in *The Times* of the 14th that a vivid display was seen from Hitcombe, on the night of the 12th, extending over a great part of the horizon beyond the Welsh coast. The aurora was visible at Suez on October 24th, 1870, and again on Feb. 8th, 1872, when it was seen there were great electrical disturbances over all the lines. During the last I measured earth currents equal to 120 Daniell cells upon the Suez and Aden cables. The aurora was preceded in each case by electrical disturbances on the line, and in the present case earth currents have been unusually strong for some days before, although during the actual time of the greatest disturbance on either lines the Suez-Aden section was clear."

THE MAGNET IN PARALYSIS.

Professor Nothnagel relates (Virchow's *Archiv*, May, 1880) some experiments he made on rabbits with the Leyden jar. He found that sufficiently powerful sparks produced a localised anæsthesia of transient nature. The extent of the anæsthesia was proportional to the density of the charge. He found that, to its quantity divided by the diameter of the brush. At the same time the motor fibres were almost unaffected, the duration of the paralysis being about the same as that of the loss of sensation. The faradic excitability was not destroyed nor even diminished. The latter was also the case where a man was struck by lightning on his right side, which became completely paralysed and remained so for ten weeks. The recovery was sudden and rapid; in two days the hand became quite normal again and remained so for six years, when suddenly both hands and feet were paralysed. Professor Three months after the occurrence he was admitted into the hospital. He was subjected to the usual electrotherapeutic means, without any benefit. Professor Nothnagel, who had read of Burq's experiments on a case of hemi-anæsthesia, tried the magnet [illegible] hand. His astonishment was great on finding that within three quarters of an hour sensation and motility were returning. Further applications of the magnet were followed by a complete recovery, and a few days afterwards the patient resumed his work. No return has been observed.

EFFECT OF MAGNETISM IN TOUGHENED IRON.

The *Lumière Electrique* states that M. Piazzoli has just undertaken a series of interesting experiments to demonstrate that magnetisation increases the toughness of iron. Holmhoeff had already proved as far back as 1866 that such must be the case by showing that a piece of magnetized iron requires a heavier greater than that of tempered steel, and that it also will have no effect on it; but it was interesting to know whether this limit was at the same time accompanied by a condition of toughness. M. Piazzoli's experiments were performed with iron wires about fourteen inches in length, stretched over supports, and covered with four magnetic spirals through which long currents were sent successively in two directions. Silent [illegible] the magnetic effects ceased to be produced or annulled in the iron wire without changing the thermic effects developed at the same time by the action of the current. The following are the results obtained with the specimen of wire employed, the weight of which was 0·209 gramme per metre (1.) When the wire had been annealed with charcoal the breaking weight was found to vary from 1,900 to 1,950 grammes, under the influence of magnetisation, and the wire had been reduced in cable of carbon these weights were 2324·4 to 1726·8 with magnetisation, and from 1761·92 to 1719·87 without magnetisation. (3.) Finally, when the wire had been annealed in hydrogen the weight necessary to break it when magnetised was from 1293·6 to 1210·1, and from 1208 to 1209·2 when unmagnetised.

Although the difference between the larger and smaller figures of each of the two series are at times contradictory to the conclusions announced at the beginning of this note, the summary of the eighteen series of experiments has shown that the breaking weight of the magnetized wire was from one to three per cent. greater than that of non-magnetized iron.

Interesting Experiment.—A simple and interesting experiment in magnetism has been introduced by Prof. Thompson. A thin plate of hardened steel is written upon, with a magnetized [illegible] pencil, is preserved by the steps in [illegible] which [illegible] to read what has been written, things are sprinkled on the plate and the plate is then gently tapped a few times. The particles of which the [illegible] fall off except those which [illegible] magnetic part of the plate marked by the [illegible] having the writing in relief.

The Earth's Magnetism.

The great physical problem of terrestrial magnetism has engaged the attention of numerous physicists lately, and it is well known that several ingenious solutions of it have been proposed. Professors Ayrton and Perry, for example, conceived the happy [illegible] which was adopted with much electricity, which being carried round on the surface of the globe, [illegible] the magnetism of the earth. It occurs now to doubt to this [illegible] however, by the mathematical criticism [illegible] Professor Perry has since found out that the surface charge required was sufficient to send a spark from earth to moon. A theory based upon the existence of electric currents flowing in the atmosphere around the earth was propounded later; and now we have another supposition, which has a better claim to serious attention than any of the rest, because it is supported by direct experiment. Starting from the idea of M. Edlund that an electric current is really an ether current flowing in the circuit, and that electrostatic effects are due to accretions and condensations of the ether, M. Selim Lemström considered that he might produce like ether current by mechanical action. He therefore made a paper tube having two concentric walls and mounted on an axis. A core of soft white iron was placed within the tube, and an exciting the latter the core was found to be magnetic, as demonstrated by two magnetometers. On now throwing the rotation reversed the magnetic polarity; and M. Lemström concludes that the relative motion of the ether in the revolving tube and the stationary core was the cause of the polarity. It follows that if the tube be stationary and the core revolved a similar effect will be produced; and hence, if a magnetic body like the earth be rapidly rotated round its axis in an insulating medium like the air, it will exhibit magnetism. Pursuing this idea into mathematics, M. Lemström arrives at an expression for the magnetic moment of the earth which agrees very well with the formula of Gauss.

Nouveau moyen de reproduire l'expérience du magnétisme de rotation d'Arago.

On peut, suivant M. Bailly, au moyen d'électro-aimants dont on fait varier l'intensité, faire tourner une plaque de cuivre, et si les variations sont assez rapprochées, la rotation semble continue comme dans l'expérience d'Arago. « Plaçons, en effet, dit M. Bailly, deux pôles magnétiques au-dessous d'un disque conducteur mobile autour d'un axe vertical, et faisons l'un des pôles ponctuel, en posant réaliser les combinaisons suivantes

Journal

Pôles [illegible] même sens [illegible] de magnétisme.

Pôles de noms contraires [illegible] Universelle

« Dans le premier cas, l'action des pôles variable par les courants induits est perpendiculaire au plan du disque, mais l'autre pôle reprenne ce disque vers le premier; dans le second cas, le disque marche vers le pôle constant; dans le troisième et le quatrième, les effets sont les mêmes tant que la rotation est de sens contraire; mais si l'un des pôles augmente d'énergie alors que l'autre en perd, les actions s'ajoutent, et, comme ces extrêmes, on peut prendre des aimants qui commencent à s'aimanter ou qui finissent. Or, supposons une série d'aimants rectilignes P, Q, R disposés en cercle de manière que leurs pôles soient sur le même plan, et réunissons dans deux les aimants placés aux extrémités d'une même diamètre du disque, en faisant passer en P et Q des courants tels que les pôles voisins soient de même nom. Supprimons le courant en P, et rétablissons-le en Q, et ainsi de suite : la rotation reconra une série d'impulsions, toutes dans le même sens, et si le nombre des électro-aimants est infini, on atteindra une rotation uniforme du champ magnétique comme un aimant tournant.

« On peut, toutefois, produire cette rotation au moyen de deux pôles seulement d'électro-aimants ab, a'b' et de deux piles, par les combinaisons ci-dessous.

1 2 3 4 5 6 7 8 9
NN ON NN SS SS ON SS NO NN
SS SO SN ON NN NO NS OS NS

« O indique que le pôle est inerte, et quand cela a lieu, le disque tourne dans le sens ab, a'b'; mais il en renverse les polarités de manière à rendre suffisante une impulsion. Au moyen d'un commutateur, on peut produire les interruptions convenables pour faire tourner le disque dans un sens ou dans l'autre.

« On augmente l'effet en plaçant au-dessus du disque des électro-aimants disposés d'une manière inverse par rapport à ceux qui sont au-dessous et dont les pôles doivent toujours être de noms contraires... »

Positions conjuguées de deux hoônes circulaires.

D'après M. W. Grant, si on dispose en face l'une de l'autre deux hobines électriques dont une jouie le rôle d'inducteur, l'autre d'induit, et qu'on déplace l'une d'elles latéralement par rapport à l'autre tout en maintenant les axes

no bearing on the subject of the high temperatures obtained by breathing through warm material on the bulb of a thermometer, for no one has yet observed that ventilets clothing will develop a less greater than that of the body it covers, viz., 98°·5.

The hygroscopic properties of different materials offer no explanation of the phenomenon, for the power of materials to imbibe moisture will not account for an increase of their temperature by becoming moist themselves.

Are my conclusions right or wrong; Mr. McNally has not shown them to be either. My facts are not the less true from being incompatible with "ascertained physiological truths," for ascertained physiological truths are only true so long as they are not controverted by other ascertained physiological truths.

My experiments show that the temperature obtained by breathing on the thermometer in the manner described is higher when his exhale is obstructed from the surface of the body, lower when the surface of the body is losing more caloric. Thus on a warm surface of my breath raised the thermometer to 108°, whereas to-day (a cold wet day) it only raised the thermometer up to 103°. Does not this seem to show that respiration is a means of getting rid of the superfluous caloric generated in the body, and that when the means of caloric cannot be got rid of by the skin it passes off by the breath?

Selenium

As the only chance of being able to transmit images of reflexion through a conducting wire, in the way sound is repeated to a distance by telephone, appears to lie in the preparation of a finely transparent sheet of metallic selenium; it may tend to advance the subject if the difficulties experienced in dealing with this substance are mentioned.

Selenium in its vitreous condition melts about 220° Fahrenheit, and can be drawn out between side plates over a lamp, to a thin transparent red film. But heated for some time it turns black and granular, apparently dissolving hydrogen, then melts only at 473° F., and is brittle and intractable. Unfortunately it is only in its crystalline state that its power of conducting electricity appears, and varies with the light under which the crystals are placed.

Procured in the usual way, electrically conducting selenium is an opaque mass of the hardness of brass, with the shiny appearance and surface of graphite. Heated, it is reduced with a sufficiency to any degree of transparency in vapour to be deposited, it is of a dull red colour, and unless in the ideal solution from hydrogenic pressure between flat polished steel plates, the deposit is always slightly profound. Selenium also dissolves freely in chloride of selenium, $SeCl_4$, and precipitates slowly in a butyrated mass of black lustrous plates. It also separates in the crystalline form from concentrated solutions of caustic of potassium or sodium.

There is some uncertainty as to whether a transparent sheet could be more easily obtained by the method of precipitation, than by some mechanical treatment. But the investigation is one that requires to be carried out with the aid of a fully equipped laboratory, and is beyond the power of an ordinary amateur's means.

To develop a successful mode of making a black substance like graphite at all moderate, requires a distinct under-standing of the reason why selenium can expose. Something more than an explanation in general terms is needed before camera pictures can be resolved into their electric currents, and again integrated upon a receiving plate.

Perhaps some of the readers of NATURE may be able to suggest a method of dealing with selenium that will produce this transparent sheets capable of conducting electricity.

London, October 16 A. T. F.

Dynastes Hercules

The reviewer of Oley's "Camps in the Caribees" (NATURE, vol. xxii. p. 529) appears to doubt the story of the habits of the large Hercules beetle, *Dynastes hercules*, told by Oley on the authority of Sprigle. If the description perfectly true, and I have myself often seen the occurrences described in the neighbourhood, where the beetle is not uncommon. In the first instance I noticed it on a branch of *Ochroma lagopus*, and the second time on a species of *Bombax*, both very soft-wooded trees. The branches in each case were about three-quarters of an inch in diameter, half an inch being formed by the wood. In both cases I saw the performance of the animal most distinctly, just as described by Oley's guide, and I took not only a piece of the severed branch with me, but secured also the severed animal. The noise is not so much produced by the cutting of the branch as by the open wings passing rapidly through the air during the motion of the beetle. I do not believe there is anything of a sexual call in the manœuvre. The beetle wants to get at the abundant juice of the young leaves. It is called in this country *corrocoyo*, or *corocoro*. Sloane, Leroy, an effect insect of the same family as *Geotrupes* and *Scarabæus* in a similar way, but chooses of course thinner branches.

An Octopus

I ENCLOSE an account of an enormous octopus which was thrown on the shore at Killare, Co. Clare, in the last great storm. As I suppose my uncle's hand very hard to read, I have copied his letter.

Ardanaile Fuynes C. G. O'BRIEN

"*Saturday, October 9, 1880*

"I am sorry you were not at Killare when a great fish was stranded on the side of the Duggerna reef on Thursday last. Its arms last long certainly broken : there were eight of them, each as thick as a strong man's upper arm, and beneath each were two rows of suckers like saucers—one row more than a shilling size in circuit. When perfect, each of the 2 arms must have been from twelve to fifteen feet long, and from the point of one arm to that of its opposite was a length of nearly thirty feet. The animal's length from the insertion of its arms to the end of its body must have been nearly twenty feet, perhaps more. Its mouth, like a parrot's beak, was as large as two joined hands of a large man with the fingers outstretched. It weighed about 4 cwt. Its head was 24 inch in diameter, about three feet long : its eyes of the size of the inner circuit of a breakfast-plate. A monster. The under colour first of the under side of a turbot."

—(*From a letter of the Rev.* R. J. GARRETT.)

SYNTHESIS OF CITRIC ACID

AS we intimated last week, another brilliant synthesis has recently been accomplished in the domain of organic chemistry. Messrs. Grimaux and Adam have succeeded in building up the characteristic acid of lemons from glycerin. Glycerin may be regarded as trihydroxypropane, $C_3H_5(OH)_3$, and citric acid as hydroxypropane-tricarboxylic acid, $C_3H_4(OH)(CO_2H)_3$. To convert glycerin into citric acid it was therefore necessary to replace two (hydroxyl) groups, and one hydrogen atom, by the group CO_2H (carboxyl). This was done as follows :—By the action of hydrochloric acid on glycerin, dichlorhydrin,

AN ACCOUNT OF EXPERIMENTS IN PHOTO-ELECTRICITY.

Telegraph Journal.

By C. H. MINCHIN, M.A., Professor of Applied Mathematics in the Royal Indian Engineering College, Cooper's Hill.

(Read before the British Association, Aug., 1886.)

Ref. 1871

(*Continued from page* 326.)

18. CASE OF INVERSE CURRENTS.—Several experiments, made at various times, led me to conclude that when cosine is in the cell, and not on the plate, the photo-electric current is in the direction opposite to that of the current produced when the cosine is on the plate and not in the cell. The observed phenomenon were not, however, marked enough to prove this decisively; and, indeed, the difficulty of determining the point is obvious, because if a clean plate is dipped into a cell containing a solution of cosine, the plate will at once take up a layer of cosine, however thin, and we shall necessarily have the two cases combined.

An experiment which seems to me to have a bearing on this question is the following :—I took a large glass cell and filled it with distilled water containing a very small quantity of cosine. The liquid became brilliantly coloured. The cell was completely covered over with black paper pasted to the faces, with the exception of a rectangular strip of one face, opposite to which was placed the plate on which the light was to fall. Two clean silver plates were immersed in the cell, and connected with the galvanometer in a loop-room. The cell was at the top of the house, and the light used was sunlight. No light being admitted, the D. C. happened to be from the shaded plates to that which was about to be exposed, and after five minutes this current had so far died out that the spot came to rest at 40 divisions from its zero position.

Now, when the screen in front of the cell was suddenly removed, the spot answered over the 80 or 90 divisions of the scale in the direction *opposite to that in which it moved by the light*, and after this initial deflection it moved slowly in the opposite direction, just as it would have moved if the plate had been dipped with an ordinary gelatine film, and its motions then appeared to answer the variations of light intensity as usual. This latter (or normal) motion was much greater than the initial impulsive motion.

Again, when the screen was suddenly replaced in front of the cell, the spot, instead of going suddenly back towards the zero position (as we should expect it to do on the withdrawal of the light) *took an impulsive forward motion over 80 or 90 divisions of the scale*, after which it moved backward to zero.

The same experiment was tried with fluorescine—a different cell being, of course, used. The same results were observed, so that the impulsive motions of the spot took place over only 4 or 5 divisions instead of 80 or 90.

It would seem to me that these observations are consistent with the supposition that the action of light on cosine and fluorescine is a cause of the production of electric current exactly opposite from those which it may generate by effecting chemical action between these bodies and metallic plates.

19. NAPHTHALINE RED.—A silver plate was coated with a layer of gelatine, and was soaked up in a testtube with a very small quantity of naphthaline red, this latter having been previously dissolved in alcohol. The layer was allowed to set thoroughly on the plate, and, when dried in a cell containing tap water, no discoloration of the water took place, however long the plate was left immersed.

Apparently, for photometric purposes, this is the best plate that I have found. A naphthaline red plate which was made last April, and which has been used several times since, is found to answer quite as at least as well as those given by it eighteen months ago.

Though these experiments are not quite so exact as those given by cosine plates, Moreover, some experiments with coloured glasses show that currents in opposite directions are produced by the red and the blue rays.

I quote the records of two experiments :—

Tune 28.—Naphthaline red. D. C. from U. to L. in cell. Spot steady at 30 divisions to right of zero. Sunlight.

No glass in front of cell. Motion from 30 to right, each opposite to 70 to left ... ... from 30 right.

Blue	...	...	...	180, ...	... 30 ...
Red	...	...	...	∞ ...	... 30 ...
Red	...	...	...	∞, right, ...	... 30 ...
Blue	...	...	...	180, ...	... 30 ...
Green	...	...	...	0 ...	... 30 ...

"The opposite results of the red and blue rays do not appear to be accidental, but this may be due to the comparative sensitiveness of the effect of the red and, and to impurities of colours in the glasses.)

Tune 28.—Same plate, same cell. Magnesium light. Spot steady, at 45 divisions to right of zero.

Red glass ...	Motion from 45, right, to ∞, left	Same direction as D. C.
Yellow, dilute ...	Motion from 45, right, to 60, to left	Opposite to D. C.
Yellow, strong ...	Motion from 45, right, to ∞, to left	Same direction as D. C.
Blue, dilute ...	Motion from 45, right, to 60, to left	Opposite to D. C.
Blue, deep ...	Motion from 45, right, to ∞, to left	Same direction as D. C.

The opposite effects of the coloured glasses were observed only when magnesium light was used. With sunlight, these opposite effects were not produced in any experiments of which I have records.

With the plate prepared nearly three months previously, I observed that the D. C. usually disappeared in about one minute after the completion of the circuit; and that on the withdrawal of the light the spot returned to the zero position in about a minute.

As a general rule, I have observed that for the production of maximum effects a very small quantity of the colouring substance (cosine, naphthaline red, &c.) must be used in the gelatine layer.

The use of sunplates will (in virtue of the comparative insolubility in water) was suggested to me by Mr. Wilson, of South Kensington.

20. INVERSE CASES.—In examining the photo-electric qualities of the Aquilles Dyes, I found that very strong currents are produced by the action of light on a silver plate coated with iodine green and gelatine. Dissolve a very small quantity of iodine green in water and shake, pour it in a dish large enough for use, and when the plate has become thoroughly dye, pour over it a layer of collodion. Then dip it a few times in a tumbler of water. After the first dip a little of the iodine green will come into the water—probably from the edges of the plate; but subsequently no visible amount will come off.

Placed, in the usual way, in a cell containing tap water, this gave a strong D. C., which died out completely in about twenty-four hours.

Tune 17, to 8, in the cell,

and this current kept the needle right against the stops. In order to bring the spot back to the edge of the scale, it was necessary to place three yellow glasses and a violet one in front of the cell.

21. MEASUREMENT OF THE E. M. F.—Twelve of the small cloisite cells with blue glass faces were employed for the measurement of the E. M. F. produced by the action of sunlight on a silver plate coated as above with iodine green. Exposed to very oblique sunlight in a window of the Physical Laboratory at University College, London, the plates of the battery were connected with a Thomson Quadrant Electrometer. The deflection varied with the intensity of the light; it did not wholly disappear when the light was withdrawn, but became steady at a definite value, and, closed for five minutes, gave no deflection. The E. M. F. so permanently been allowed to disappear by closing the circuit of the battery, and tested by it after closing the previous night. In this observation the reading was E. M. F. 0·1 single cell observed was about the $\frac{1}{200}$th of the E. M. F. of a Daniell's cell.

The battery was left covered up in charge of Mr. Grant, the Assistant, and he kindly made further measurements whenever better conditions of sunlight offered. The sunlight in one of his observations brought up the E. M. F. to $\frac{1}{40}$th of that of a Daniell.

22. OTHER SUBSTANCES.—Although I have now described the most striking of the results obtained, several other substances have been used. Foremost among these I may mention Fuchsine, an exceedingly unstable body, a trial of which was recommended to me by Professor E. Wiedemann. The ease with which it is soluble in water renders it objectionable for coating a plate. But when dried on a thoroughly clean plate, which is then dipped into a solution of iodine, a film is formed on the plate (silver), and gives good currents by the action of sunlight.

Fluorescine, used like cosine, with silver or platinum plates, gives poor results.

Of course the action of light on a silver plate, coated

76

INFLUENCE OF THE GALVANIC CURRENT ON BACTERIA (P. Cohn and B. Mendelsohn).—The authors carried out their experiments to verify the assertion of Schiel, that the galvanic current prevents the development of bacteria. The results were that a feeble current from one pair of elements had no perceptible effect; a current from two elements rendered the solution inactive at the positive pole; a current from five, sustained for twenty-four hours, completely sterilised the whole solution, and deprived it of its power to infect another solution. The solution at the positive pole was first bleached; with the stronger current the liquid became acid at the positive and alkaline at the negative pole. The induction current had no perceptible effect on the bacteria.—*Ind. C.*

Science N. 196

An Explosion of Electrical Phenomena.

Mound, Iowa, Oct. 9.

To the Editor of the Journal of the Telegraph: I S

Last evening a noise very distinctly resembling the reverberation of distant thunder was heard in my office. Upon investigation I found that it came from my telegraph table, although I could not discover that my instruments had anything to do with it. Opening the key did not cause the sound to cease, and putting my ear to the table I could distinctly hear our night train despatcher calling offices on circuit No. 2, I telling on No. 1. Circuits Nos. 1 and 2 have no apparent connection with each other or at all, although both instruments are on the same table, one being on one end of the table and the other at the opposite end. We tried it several times and it always worked the same. Will you please explain how the sound could be carried in that way?

My office is situated twenty-one miles south of the train despatcher's office, and he was working south on circuit No. 2.

W. E. F.

Lisbon.—It may have been caused by short circuiting of main and local connections in one of the relays, by defective insulation between bells and coil, the latter touching the armature.]

SCIENTIFIC PROGRESS.

Seeing by Electricity.

A correspondent of the *Scientific American* says that the description of "seeing by electricity" is not altogether new. The correspondent, W. E. Sawyer, of New York, writes as follows: "Early in the fall of 1879, I constructed, from principles and even the apparatus described, visible objects at a distance through a single telegraphic wire were described at No. 21 Cortlandt street, New York, to James G. Smith, Esq., formerly superintendent of the Atlantic and Pacific Telegraph Co., and now of the Continental Telegraph Co., and to Messrs Shaw & Baldwin, telegraphic constructors, now connected with the Clectic Telephone Co. At that time the writer was engaged in perfecting an autographic telegraph by which many characters were daily transmitted by telegraph over a single wire.

"The correct consciousness of this discovery in these different directions, each undoubtedly independent of my own experiments, show how the same idea often arises in separate minds. There is no likelihood of any of the rights ever being refused to grant, for none of the difficulties in the way of all of the plans are insuperable, as will be apparent from the following reasons:

"1. The action of light upon selenium in changing its electric conductivity is slow—although now discoveries may remedy this fact.

"2. To convey with any accuracy an image, one even as small as to be projected upon a square inch of surface (I am speaking now of his apparatus you describe), would necessitate that this inch surface should be composed of at least 10,000 insulated selenium points, connected with as many insulated wires leading to the receiving instrument, for the variation of the 10th of an inch either way will 'throw a line out of focus.'

"3. The most delicate apparatus would not indicate a change in resistance by the projection of light upon merely a selenium point.

"4. Isochronism is unattainable, as required. The method I proposed involved the isochronous movement of the separate instruments. The transmitter consisted of a coil of fine selenium wire in a darkened case, having a diameter of say three inches. Light from the image to be transmitted was to be let into the transmitter and upon the selenium coil by a fine tube which, starting at the periphery of the circle, would draw concentric imaginary spiral lines until reaching the center of the circle. The light emitted or reflected from the image to be transmitted would effect the selenium just in proportion to the brightness of the image at the different points within the compass of the circle traversed by the imaginary lines drawn by the opening in the tube.

"The receiver consisted of a darkened tube, having an inside diameter of three inches (corresponding to the transmitting circle) with its sides and bottom absolutely black. In this tube, drawing exactly anything lines just as the tube in the transmitter, was a blackened index carrying two fine insulated platinum points very close together connected with the secondary wire of a powerful induction coil, the primary wire of which constituted a part of the main wire leading to the transmitter.

"The transmitting ray of light and the invisible index in the darkened receiving tube were to start at the periphery and describe their spiral motions in exact synchronism. The center should be reached, and the synchronism sufficiently great it is obvious that as the intermittent spark between the receiving platinum points could not have ceased to affect the retina until the last spark, with the index at center, would have been produced, an exact image of the object before the transmitter would be reproduced before the eye of the observer placed at the darkened chamber of the receiver.

"But the trouble is to make the selenium sufficiently active, *and to get the isochronous motion.*

Science July 20. 1881.

A curious thing occurred lately in the works of M. Fleury, at Cette (Herault). The feed-water of the boiler giving much incrustation, M. Fleury was advised to put into the boiler some fragments of zinc as a de-incrustant, and did so. In a few days, spite of filling, the steam-boiler began to work very badly, the piston catching a great deal, and it soon became necessary to stop and make examination. The piston was found to be covered with a thick adherent layer of copper. It was put on the lathe, and at certain convex projections, the metallic layers were so thick that the tool worked in copper alone. The explanation given by M. Fleury is this. The boiler was connected with the engine by copper pipes. Particles of zinc carried off by the steam would form with the copper a multitude small galvanic couples; hence the transport of copper to the piston, which would principally attract them by reason of its motion, and of the heating produced. It is remarked in *Les Mondes*, that the eminently electric properties of expanding steam may have helped in development of the phenomenon.

77

instrument, but to a lever, n, on which it works stiffly, so as to retain any position in which it is placed. Lever n works contiguous has a limited range of motion, to one end of which it is elevated by a spring; slight pressure with the finger, moves it and its attached mirror, so as to throw the light to and off the object in a succession of long and short flashes by which letters and words may be indicated. Flashes may also be given by moving the thumbpiece H held in the hand.

The above instrument answers well for all positions of the sun except when very low behind the observer's back, for this case another mirror is provided by which the light is reflected on to the mirror, A. Messrs. T. Cooke & Sons, York, are sole makers of this instrument.

AN ACCOUNT OF EXPERIMENTS IN PHOTO-ELECTRICITY.

By G. M. MINCHIN, M.A., Professor of Applied Mathematics at the Royal Indian Engineering College, Cooper's Hill.

(Read before the British Association Aug. 18th.)

1. TWO OBJECTS OF PHOTO-ELECTRICITY.—In the study of the electric currents produced in various ways by the action of light, I have had two objects in view, viz.:—

(1.) *The production at a distance of effects due, in the first instance, to photographic action of light;* and

(2.) *The continuous daily registration of the intensity of sunlight of any selected wave length.*

It is at the outset evident that for the solution of the latter problem the action of the light, whose intensity is to be measured and registered, must be received on some substance whose chemical composition is either unaltered by the light, or so slowly and slightly altered during the period of observation, that the magnitude of the change may be neglected.

For the solution of the former problem it occurred to me, in the first instance, to receive the photographic action on plates coated with the silver salts in ordinary use among photographers; but I do not now think that it would be necessary to work exclusively with these substances, and if the use of them can be to any extent dispensed with, a corresponding gain in sensitiveness would, since they are permanently and very rapidly decomposed by luminous action.

2. LUMINOUS ACTION A SOURCE OF ELECTRICITY.—In 1873, Professor Young, from the experiments of Hesehyel and Clarke, that electrical currents can be produced by the action of light, discovered each two clean silver plates exposed one to the vapour of iodine, plunged both into a cell containing a conducting liquid, and completed the circuit through a galvanometer. The cell being completely covered in the moment the circuit was completed, a strong current was set up. This current disappeared after about 24 hours. Then, on illuminating the sensitised plate, an intense current was generated by the light.

Grove used a prepared daguerreotype plate inclosed in a box filled with water, having a glass front with a shutter over it. Between this glass and the plate was placed a gridiron of silver wire, and, on completing the circuit through a galvanometer, a current was generated by the action of light on the daguerreotype plate. (See the *Correlation of Physical Forces.*)

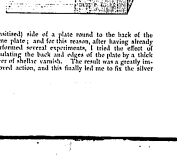
Grove also found that when two clean platinum plates were immersed in a cell containing acidulated water, and one of them was exposed to light, a current was produced. On the light was allowed to fall on the plate three days or of course, the current which is always produced by the immersion of two plates, however similar on each, ceased in making them, in any liquid. This current I am in the habit of speak of as "the disturbing current," since it is produced by some other agency than that of light; and I shall frequently refer to it as the "D. C." for shortness. The current produced by the action of light on one of the platinum plates was found by Grove to be always in the same direction as that of the D. C.; and he found, moreover, that the current produced by the rays was greater than that produced by red.

Currents of this latter kind may be produced by the agency of light in several different ways. For instance, the two platinum plates will give the current in question if they are immersed in common tap water. Again, the two clean platinum plates may be replaced by two clean silver plates, and we shall obtain still stronger currents by the action of light on one of them. No doubt several other metals would be found to give similar results.

In such currents—viz., those generated by the action of light on any unoxidised metallic plate immersed in a liquid, in presence of a similar plate unexposed to the light—I shall be at present designate as "Grove's currents." They are exceedingly small compared with the photo-electric currents which we shall be occupied.

3. PLATES EMPLOYED.—Since the substances to be acted upon by light were, in my first experiments, those of silver, I chose silver plates in order to obtain as much interference action in the cells as possible. At first the plates were simply stiff pieces of silver foil, about two or three inches long, and one or two inches broad. But it appeared at least possible that much of the current was lost by passing from the excited (or

Fig 4.



sensitised) side of a plate round to the back of the same plate, and for this reason, after having already performed several experiments, I tried the effect of insulating the back and edges of the plate by a thick layer of shellac varnish. The result was a greatly improved action, and this finally led me to fit the silver

78

Magnetic Attraction in Iron Ships.

THE South Australian *Advertiser* prints the following interesting communication from a correspondent:

Before the *Hecate* left England, Captain Wild read in a paper a suggestion to nullify the local attraction on board iron vessels by means of an earth compass, the simplicity of which is its chief recommendation. It was claimed that a complete envelope of earth would so far protect the attraction of the compass by the addition or absorption of local magnetism, that deviation tables would be unnecessary. The *Hecate* was fitted with binnacle and standard compasses on same, both of which varied from one and a half to three points, according to the direction of the ship's head, before leaving, the master furnished himself with the necessary earth to form a mound about an ordinary ship's compass. Accordingly this half cask was procured, directly over the compass and the compass was buried deep in the soil, so that the direction of the needle might be accurately observed. During the voyage the most careful attention has been paid to the compass, and the result has proved the complete efficacy of the plan adopted, and that a compass so fitted is as much to be depended on in an iron vessel as though it were in a wooden ship. The experiment was deemed of sufficient importance to attract the attention of Captain Blanche, the inspector of compasses, who devoted some part of Monday to making experiments, and has since verified the Captain's statements. Sailors alongside the wharf the standard compass—one and a half points wrong, and the binnacle compass two points out; that on the earth box was true as the needle to the pole."

1875

ANOTHER new property of selenium is claimed as the discovery of M. Blondlot. He states that when selenium is rubbed upon platinum, each metal being connected with a terminal of a capillary electrometer, a current is observed. This current, which is observed to pass through the electrometer from the platinum to the selenium, appears therefore to differ from the thermo-electric currents discovered by Becquerel, and which were always in the same direction at the thermo-electric contacts which would have been produced had the surfaces of friction been suitably heated. The term thermo-electric current of a selenium-platinum pair is, according to M. Blondlot, from selenium to platinum at the heated junction. One curious point stated by M. Blondlot is that its deflection whatever is obtained upon the capillary electrometer, whether the connection be made between two tenderers, between a vessel and an insulator. The electrometer in the selenium-platinum circuit indicates a diminution of potential about equal to that of one Daniell's cell.

Engineering Jan 7 1876

"It is a familiar fact that some ordinary kinds of paper, well heated and rubbed, show distinct electrical properties. Mary Wickamora has shown that Swedish filtering-paper, after a certain preparatory treatment, presents much more intense electric properties. A strip seven centimetres long, &c. It is proper to mix into a mixture of nitric and sulphuric acids (equal volumes), as for making gun-cotton. Then it is washed well with water and dried. It should be rubbed on wax-cloth to develope the electric charge. (Jour. f. p. C. [2] 7, 127.)

Eng Mech Jan 21 1876

A CONTRIBUTION TO THE ANALYSIS OF ELECTRIC DISCHARGES. W. Holtz.—The electrodes (tin-foil points) between which the sparks of an induction apparatus were striking were made to revolve up to 2,000 times per second in an electric field of 12 c.m. diameter. When the distance traversed by the sparks is very small the electrical image of the sparks is greatest. It is reduced by diminishing the capacity of the exciting elements and the number of turns of the two wires in the induction coil, or by increasing the resistance of the air. The image consists of a great number of parts separated by intervals, and is of a violet light anterior coil, followed by white violet tints, reddening in length. On connecting the poles of the induction apparatus with Leyden jars the longer the jars the greater the total extinct of the image of the spark and of the layers is shortened; the violet tints disappear, and the red tints become brighter. This shows that the intermittent luminous phenomenon does not depend on an intermittent excitation of molecules within the coil, but merely on an intermittent discharge of its end-surfaces: for with increase of the polar surfaces, and with production of the distance traversed by the sparks, the quantity of electricity of the reversal discharges is increased at the cost of their number. Exactly similar phenomena as observed on discharging Leyden jars with the intercalation of moist cards when the ends of the cards are connected each with a smaller Leyden jar just before the tracks of the sparks. The length of the entire image increases with the size of the surface of the layers.—*Göttingen Nachrichten*, iv., p. 315.

ON THE ELECTRIC DISCHARGE AS A CONTRIBUTION TO THE EXPLANATION OF THE PHENOMENA IN GEISSLER TUBES, AND TO THE REFRACTION OF THE PHOTOMETRIC RAYS. Dr. Oberbeck. (Pogg. Ann.—Jubelband.)—Tubes of 10—20 c.m. in length and 1—2 c.m. in width were closed at each end with cards, through which were passed copper wires. Bronze-powder was introduced; other finer powders which were tried adhered to the sides of the tube under the influence of the discharge in consequence of static charges. One wire was connected with the positive conductor of an electric machine, whilst the other permitted the supply of electricity to escape into the air. In certain cases the electricity was furnished by a charged Leyden jar, and the pressure of the air was that of the atmosphere. The bronze-powder displayed three very beautiful stratifications, which differed in their arrangement according to the original position of the powder. Around the positive pole there was formed a large space of air at first free from the powder, which was later collected at the negative pole. If the current had been allowed to pass for a time and the poles were then changed the strata disappeared and the chief part of the powder collected in the middle of the tube, probably owing to its static charges. The phenomenon agrees closely with Quincke's.

The author compares these distributions of the bronze-powder with the stratification of gases, showing that both are influenced by the same circumstances, such as the quantity of electricity passing at each discharge, the width of the tube, the charge of the outer sides, &c. With a repulsion of the particles similar to one the electrode could here be directly observed, the author considers that the stratification in Geissler's tubes depends on mechanical causes, as is assumed to be the case in Faraday's dark space. Hittorf has observed that the condensed strata are luminous. He explains the stratification from the fact that the electricity enters the tube, the sides and the gaseous molecules become saturated, and are repelled from the electrode and from the sides. The electrode moves the gas to the negative pole, and the sides of the tube impel it more or less towards the axis of the tube. From the reciprocal action of these forces results a strata like the disc-figures bronze-powder is chiefly accumulated at the negative pole, the author concludes that the maximum density of the gas in Geissler's tubes is found at the negative pole. He seeks to explain the stratification in flames, the figures of Lichtenberg, &c., on the same principles. The author appends some remarks on Crookes' experiments, which he explains in accordance with his views, and thus refutes the hypothesis of the fourth state of matter, but without submitting it to any thorough discussion.—*Beiblätter* (Wiedemann's), iv., No. 12.

79

EXPERIMENTAL INVESTIGATIONS OF CHANGES IN THE ABSOLUTE TENACITY OF IRON WIRES PRODUCED BY THE ELECTRIC CURRENT.—G. Hoffmann.—An increase of tenacity was observed in iron wires after being traversed by the current. Wire which in its original state was able to support 68 grms. after a three hours' passage of the current supported 230, showing an increase of 238 per cent. With the elongation of the section of the current the increase of tenacity became greater till it attained a maximum which was reached earlier in some wires and later in others. Thus wires of 0·19 millimetre in diameter after a three minutes' passage of the current showed an increase of tenacity of 58 grms. after 12 hours' passage, 24 hours 50, another wire of 0·31 millimetres diameter after three hours showed a gain of 12 grms., after 6 hours 23 grms., and after 24 hours no further increase. The gain chiefly concerns the increase of tenacity in equal time-elements proportional to the strength of the current. The stronger currents this law is no longer realised, owing to the heating of the wires. Thus in the case of a wire of 0·19 metre diameter a 12 hours' passage of $0·07$ units of a deviation of 4° gave an increase of strength of 56 grms., one of $0·28$ grms., and one of $0·56$ grms. During the actual passage of the current the increase was greater. The author considers that the increase of cohesion is favoured by the heat evolved by the current, but that the current itself plays an essential part.—

THE polar difference in luminous phenomena of the discharge of electricity through gases were considered by Wiedemann and Rühlmann as possibly due, in part at least, to a gas layer (more or less condensed) on one electrode. Supposing that other kinds of envelopes with like action would essentially affect the phenomena, Herr Holtz has been able (*Wied. Ann.* No. 11), by covering one electrode, e.g. with silk, or (indirectly) sensitised silk dried before it, to verify the, and (since both solutions, in some cases, the other phenomena.

IN a series of experiments recently re-searches, by Herr Geissler, of Bonn, Herr Hittorf has more investigates the phenomena which take places in a space of the transmitted that the green phosphorescence of glass appears with the discharge from the cathode, there are, not only, two general cathodes. He has met with a new form of electrical illusion, not to be classified either with the mechanical repulsion in collision of pendentic masses, or with electrostatic or *elektrodynamic* repulsion. (An abstract of the memoir appears in *Wiedemann's Beiblätter*, No. 11.)

THE TIMES OF ELECTRICITY.—Mr. Alex. Adams, one of the officers of the British Post-office Telegraph Department, has discovered the existence of electric tides in telegraph circuits. By long continued and careful observations he has determined distinct variations of strength in these earth currents, which are invariably present on all telegraphic wires, following the different diurnal positions of the moon with respect to the earth.

New York Times, September 9 1881.

A SAFFRON-COLORED SKY

A CURIOUS PHENOMENON AND ONE WIDELY EXTENDED.

BEGINNING IN CANADA ON MONDAY, IT SPREADS OVER NEW-ENGLAND AND PART OF NEW-YORK ON TUESDAY.

From the Toronto Globe, Sept. 6.

The curious atmospheric conversation all over the city yesterday afternoon and evening was the weird and morbid appearance of the sky. Early in the forenoon the mercury had risen above 90° in the shade, and although the air was somewhat sultry, the sun was unobstructed long after the darkness had commenced on the morning in the city as ordinarily still being as high as 30°. At 2:30 o'clock in the afternoon the whole southern heavens assumed a rich orange hue, and the rest of —s sky a yellow. The orange deepened and extended as the day advanced, till at 5 o'clock the heavens presented the appearance of an orange dome of extraordinary beauty. The streets and buildings were an orange tint; in fact, nearly everything looked as though viewed through an orange glass. The sun was now fullest, and instead of its usual yellow, turned a brilliant white—almost as white as the electric light. As sunset approached the orange hue deepened on old and old, and the streets were filled with an increased population gazing at the strange, weird glory of the scene, and including a full survey of specimens. Some of them terrifying—as to the cause of the unusual phenomenon. Such fear was held removed by no means. Others said it was a solar eclipse. Perhaps the most rational is an opinion that it was a dust haze in the upper strata, and thousands took a more serious view of the matter, and thought the Almighty angry.

The world is now all dressed in black,
The sun has gone to sleep,
The moon is pale with fear, alack!
And day is dark as night within doors.

Similar remarks were heard on the streets yesterday, and produced a deeper impression than the occasion warranted for the fact of the matter is that the people have learned that the phenomenon was caused by the forest fires in the Northwest, and not at all, but however, the anxious looks were not spread of hurt. Even in Montreal, the Province was visited with the same sight, and the fires in the woods did not destroy the city, and dread that the hour might succeed to avoid, a feeling of irreligiousness. Perhaps it was the fact that the sun was in the zenith at the time, and not in the west, as it usually is at sunset, that was wanting to produce the effect. At a meeting of the Board of Trade, the subject was discussed, and with one accord all came to the conclusion that the sky, which was lit up as though with sun-colored glass, was caused by the smoke from the forest fires. Mr. Gilmour, of Gilmour & Co., remarked that the whole of the gas and lamps all over the city had been lighted at 5 o'clock, and that for half an hour the streets were in a state of darkness, or red, and dangerous, and the usual darkness of midnight prevailed for a time.

From the Boston Journal, Sept. 6.

Superstitious people who were disposed to look for their evil forebodings in the sky last night found the gloom had come and Neither Shipmen's prophecy nor Mother Shipton's prophecy of a fiery end of the world. The sky was of a dull, sickly yellow hue, and the sky but the appearance of a fiery end of the world. The sky was of a dull, sickly yellow hue, and the sky but the appearance of a fiery end of the world. Every object assumed a peculiarly ghastly appearance. Every face looked pale and sickly, and the whole city presented a picture of unusually solemn and gloomy aspect. After a few hours the sky assumed a darker hue, and the fog in a twelve foot, and towards evening the fog began to lift, and

Menlo Park Scrapbook, Cat. 1029

No. 19. "Phonograph"

This scrapbook covers the period April-July 1878; there is also one clipping for June, 1877. Most of the clippings relate to the phonograph, but the book also contains material about the telephone, microphone, and electric pen. There are also several articles about Edison and Menlo Park and, on page 110, copies in Edison's hand of two telegrams. The book contains 182 numbered pages.

Blank pages not filmed: 170-171, 174-182.

THE TELEPHONE—THEORY AND PRACTICE.

[1425].—I have, almost from the first, read the articles and letters appearing upon the telephone in your invaluable journal, and derived much useful information from the various hints and suggestions from time to time made. In common with so many of your readers I have made several experiments with a view to improving the efficiency of the instrument, and although as yet I have failed to accurately measure it, with any little success, the result of some of these efforts has caused it to throw light upon certain matters previously unnoticed in your columns, the facts may, perhaps, be of some interest. I made up to the state of the instrument described by Mr. Preece in the morning instrument. In fact, a sort of molecular vibration and consequent vibration theory controversy seems to have arisen. While admitting that there is not yet sufficient for the former, the latter theory will, doubtless, be eventually adopted as the real explanation of the phenomena.

Experiment conclusively proves that magnets affected by even the weak induced currents, sufficient to produce sound in the telephone, also make a very faint effect upon the receiving magnet itself. A certain tension seems of prime help to be required to bring out the best effects, and the receiving magnet from which the lid has been removed. The thread holding the magnet should be tied to this turn of wood, leaving their ends resting on either side of the case. On passing a current from a very weak cell (that will just cover one penny) the magnet attracted the lid will be heard every time contact is made and broken, and by varying the resistance a point can be found at which the lid will be held down by the attraction of the molecular theory. Much valuable information on this point seems to be observed in the construction of all electrical apparatus would have prevented the occurrence of cases of determinate failure.

Material for making these experiments, and the results obtained, I have found serviceable, and for this I am indebted to Mr. Preece, whose kindness in this and other matters I am pleased to have this opportunity of acknowledging

2

CONDENSED MYTHOLOGY.

VULCAN.

Vulcan was the village blacksmith, about whom Mr. Longfellow has written some very clever verses. He was god of the fire and the forge, and earned his bread by the sweat of his brow. He was a rapid workman, but back files of the Northtown *Herald* make no mention of the number of horses he could shoe in an hour. The local news was not gleaned so closely in those days.

Vulcan was lame and ugly. When, at a millinary or a fireman's fair, a gold watch was voted to the handsomest man and a leather medal to the homeliest, Vulcan always got the medal. He was so lame and ugly that his mother, in shame, cast him from heaven into the sea.

And she was not arrested!

A couple of Oceanids, named Eurynome and Thetis, took pity on Vulcan and tended him for nine years in a deep grotto of the sea. How he escaped catching a fearful cold and dying of pneumonia, living in such a damp place, is little short of a miracle. He must have had wet feet pretty much all the time. For their kindness to him, Vulcan made the Misses Thetis and Eurynome many ornaments and brica-brac things, some of which the girls stuck full of Kensale pictures and placed on the parlor mantel.

Becoming reconciled to his mother Vulcan returned to Olympus under the guidance of Dionysus.

Another account says it was his father who treated Vulcan so cruelly. One day Jupiter and his wife quarrelled over the question who should get up first and make the fires—or something that way—and when Vulcan came to the assistance of his mother, Jupe seized him by the foot and hurled him from Olympus. Nine days are told, fell for a whole day, but slighted at sundown as an ale, with but little breath in his body.

We should think so. The wonder is that he was not killed outright. If he fell nine forenoon he must have lost all the money out of his pockets before reaching terra firma.

Some writers say it was from this fall that he became lame. And we are willing to believe it. Nowadays a man can't fall from the roof of a four-story house without being lamed for life. And if he were to fall a whole day, the rate in was striking that would be, of any service to him after alighting would be a funeral.

Vulcan was supposed to have his forge in the fiery mountains, and the smoke and flame which broke forth from the chimneys of his shops. This may be one man's shoulder's think he would secure much custom by setting up business in such an out-of-the-way place. His principal employment was forging thunderbolts. Ancient writers don't inform us where he found a market for such bolts. If he were still in the business, he might dispose of large numbers to our politicians, who often yearn for red-hot thunder-bolts to hurl into the ranks of the opposition.

Vulcan built himself a gorgeous temple palace on Olympus in which was a huge workshop with twenty cunningly devised pairs of bellows. It is to be presumed that he worked all these himself, for it is not on record that his journeymen ever struck for higher wages. Vulcan was the Pat. Elliman of the gods. He constructed tripods which moved of their own accord into the banqueting chamber, and then returned to their places after the meal was over. Such pieces were sources of ingenuity, but they had their objections. Guests who imbibed too freely of the nectar of the gods, and retired under the table to sleep off their wretched, would have their weakness and bodies exposed when the tripods mechanism.

But the most wonderful then the walking tables were the golden statues of maidens with which Vulcan made to assist him in waiting and lessened on them speech and motion. They were worth their weight in gold. Edison's phonograph is an insignificant humbug alongside of these talking maidens.

Despite Vulcan's deformity and ugliness, the beautiful Venus became his wife. She had several other husbands, however, and evidently believed that variety was the spice of married life. Vulcan was short in the leg, but that wasn't an inconvenient as if he had been "short" in the pocket-book. He was lame and homely and only a blacksmith, and yet the Homers worshiped him. That warm regard for the deformed god will be understood when we state that he was not a member of the 45th Congress and never wrote humorous paragraphs.—*Terre-haven Herald.*

ECHOES FROM THE PHONOGRAPH.

What Mrs. Burstingtape Heard After Three Days' Absence from Home.

It happened that Mrs. Burstingtape was taking dinner at a friend's house, and Mr. Burstingtape was irascible. As matters had predicted that she should not get beyond soup before the baby would be screaming for her presence. And then, said he, to himself, if she must go, he would neglect his office, and he would go to the opera, and he would get home in time for supper, however, she succeeded in late to be present at the dinner party, and Mr. Burstingtape was obliged to content himself with three days' absence from home. He consoled himself by going to the opera, and he had a very pleasant time of it. Then he went to the office, and he had a very pleasant time of it. Then he went to the office, and he had a very pleasant time of it. Then he went to the office

Boston Weekly Globe Oct 19

THE MAN WHO INVENTS.

TOM EDISON'S TALK WITH A "POST" REPORTER.

The Wonderful Phonograph and Its Eternal Voice—Description of the Man of Genius—What he has Accomplished—The Key of Silence Only Touched.

Hearing that Mr. Thomas A. Edison, the world-famous discoverer of the phonograph had arrived at the Smithsonian Institution yesterday, with a specimen of his instrument, The Post reporter, then on duty there, hurried from the monologues of the savants to have an interview with the most wonderful inventor of the world. Catching a glimpse of him, the reporter followed him to the outside, where the great discoverer was found looking intently around him, apparently interested in a study of the trees, the shrubbery and the blue sky. Suddenly he darted off, as if determined to more closely examine specimens of the white pine that springs from the covered point of one of the walks. As he reappeared, coming slowly back, the reporter noticed he was rather under the medium size; about five feet seven or eight inches high, and marred with a kind of listless gait, as if tired or meditating. His forehead is round, not very high, moderately full in the temporal regions, indicating a prominence of the organs, yet not especially noticeable for expansion. His hair is thick, but white, his eyes, of a decided brown hue, and the face is bare of beard. His eyes are grayish-blue, clear and bright, and in conversation brighten wonderfully. The nose is large, standing out boldly from the face, but as it is was looking into the future for its success—an inquisitive member, could not an encounter—one. A large mouth where smile is a pleasure see, a square rather prominent chin and a white skin, complete the facial description. His manner is quiet, modest and retiring, exhibiting a lack of egotism or presence at once refreshing and marvellous in a man who has reason to be so justly proud of his fame and his achievements. Yet while he is talking you are conscious that there are tremendous potencies in the plain-mannered gentleman before you. "Can I interview you, Mr. Edison?" said the Post reporter, timidly.

"Yes. What an interview with the phonograph wins without a report," he said, pointing to the not words of wins that ran high in the cylinder. "Mr. Edison, I have been told that when the combination, 'I have been told' occurs in a newspaper report, but when I went over to this lecture I found you could see no more than I could hear. Naturally enough the inventor has no eyes for trees or flowers, and I suppose you are quite as oblivious when are concerned.

"Let me, like all the rest of the world, congratulate you on your discovery of the phonograph, Mr. Edison." The Inventor shook the reporter's hand, blushed like a girl and modestly acknowledged the compliment.

"Can you a long time in perfecting the discovery?"

"Oh, no; I had thought of the idea vaguely many times, long before I undertook to work it out. The idea is fascinating, one, and this, too, fascinates my way had probably occurred to many people perhaps for centuries. But when I undertook to realize it, and make it a success it came out pretty right very easy. It is a very simple idea when you stand to look at it, and the wonder is it wasn't discovered before."

"It walked for Edison, and walked in," suggested late talking the sleeve of his coat.

"Experiment was doubtless pleasing, but the fascinating tendency of the men caused him to shrink from pursuing his own project.

"What a pity you hadn't invented it before. Then is only a matter of interesting her and her age, she would have liked the invention of Edison, their failing voices again, a miracle your phonograph makes possible."

"No, I don't think the world was ripe for it before. Why, I wanted to get it patented in South America, and my agents spoke to consuls in Mexico, Peru and other places, but were advised not to go there. The people were too ignorant, they deemed generally to receive it. I would destroy the whole system of the machinery of the civilized and such the agents as the regular line."

"Had you any thought of coming to Washington?"

"Not until yesterday, when I got a telegram requesting me. They are a pleasant set of fellows in Washington. Some don't think full of clothes, though."

"They don't really seem to care for the tailor, don't they?"

"O, they've got on their good clothes now. But see them at work, or they come into my laboratory, they don't look as nice as they do to-day, but they have lots more fun in them. I remember when Senator Thompson, when he came to see me, had on a suit of clothes, I told you. He removed his coat, vest and collar, his cuffs and shirt and greasy, the collar that I gave his glove his cuffs, and he looked as if he had boiled eggs for it. And that was his business suit, too."

"When do you give an exhibition on your phonographs?"

"Not to the public. Have you ever seen it? Well, come in and I'll show it to you." And leading the way, he entered the laboratory, followed by the secretary, editor, uncovered phonograph "Sound Writer," and began to explain:

"Here the phonograph, you see, is a thin disc or diaphragm of iron, beneath which is this fine steel point, which moves up and down in the vibrations of the disc. Beneath this is the revolving cylinder, on which is this spiral groove. As the disc vibrates the cylinder is a screw, the distance between the grooves being the same as the distance between the vibrations of the disc. Now, when I speak into the mouthpiece the vibrations of the voice send with a sheet of tin-foil — just will see it operate by and by—and when the cylinder is revolved the steel point presses into the tin-foil and the spiral groove. If now the diaphragm is thrown back by the voice the steel point will make a series of indentations in the tin-foil grooves, corresponding to the sounds uttered. On coming over again the same groove with the steel point, by the indentations in the tin-foil cause the diaphragm again to vibrate precisely as at first, thus reproducing the sound originally made. The vibrations of the voice you first used is returned to you in whatever shape you may desire. Your words, for example, are preserved in the tin-foil, and will come back upon the application of the needle. Now, you see, the whole process is exactly the same tone of voice you spoke them in."

"Are you ready, Sirs?"

Seeing as the tin-foil lacks. This tongue-less, toothless, gumless instrument, having no other power, deems voiceless matter, nevertheless utilizes your tones, and centuries after you have passed away, and centuries after you have mouldered into dust will repeat your words again, your very tones, your very voice. You, your very little thought, every fond fancy, every calm thought that you chose to whisper against the thin iron diaphragm.

"Ready, Sirs?"

"Ready, you, Mr. Edison?"

"Very ready."

"I am glad for this; and I hope to astonish the world yet with things more wonderful than this. I think the world is on the eve of grand and immense discoveries, before which the discovery of Columbus pales the record of the past will be insignificance. This is a very poor invention of the phonograph. You see how simple the invention of this idea, and how simple the idea itself; and yet, after all, is useless."

And the reporter, turning away to record the utterances of the sage in the room, suggested, thought of that passage of Holy Writ which, with very little thought and every rule, would Judgment Hour. Does the Recording Angel still hold a Deleted Phonograph, against whose spiritual diaphragm some mysterious other presently record a human life?

Scientific American

Marvels of the Phonograph.

(San Francisco Post.)

The phonograph is the latest lunkhead thing directed by science against the whole inconsequence of society, and this paper would deem itself remiss in its duty if it did not warn the public against the fraud. Mr. Edison, who is the inventor of this instrument of this fact and dastardly nefarious invention. Everybody knows how the world wonder the strange process that is useful and beneficent discovery has been under. We are all familiar with the fact that instead of being received with the kind welcome which scientific inventors must who wisely consecrate their lives and efforts with a suspicious has usually received similar tests the condemnation of ostracism, and the fact that Mr. Edison has made a development of his kind because a halt and shown upon the ludicrous runs known enough to be a warning to all who are tempted to imitate. Edison's invention is a very simple affair, consisting of a cylinder covered with tin-foil, on the outer of a cylinder, and the result intercommunication that "baby has cried" into a mouthpiece, or that the hymn singer hasn't a voice, or that the preacher is a bore, is recorded on the cylinder, whereupon the machine can be set in motion and the instrument can be obtained at ten minutes interval. Now, it is evident that such an instrument is useless and other mechanical contrivances have been invented which are of real value. Take the telephone, for instance. But the absurdity of this phonograph is not to be realized upon unless the phonograph is actually put in operation. Then the fraud of Mr. Edison's device for the manufacture of machines is as instrument which automatically records and reproduces the human voice, and also other mechanical sounds, such as the whistle of a steam engine, the whistle of a locomotive, the whistle of a steamboat, the whistle of a steamboat, the whistle of a steamboat

1878. Boston Sunday Herald.

A WONDERFUL GENIUS.

Interesting Reminiscences of Thomas Alva Edison.

One of the Greatest of American Inventors.

A Life of Eccentricity, Study and Usefulness.

The inventions of Thomas A. Edison are the wonder of the world; he has done more than any other to perfect and advance the various systems of telegraphy, he has at work with indefatigable zeal for the accomplishment of other inventions and improvements. Sketches and reminiscences of his life therefore are interesting to all connected with the use of electricity, and not only to these, but to the world at large, which he has so greatly benefited.

His ancestors came to this country in 1731, Thomas Edison was a prominent local official in Manhattan Island during the Revolution, and his name appears on the Continental money. The race is long-lived. Edison's great-grandmother lived to be 99, and his grandfather 103 years old. His father, Samuel Edison, is now living, aged 76, and in perfect health. His mother, Mary Ellen Edison, was also of Dutch parentage, but born in Nova Scotia. She was finely educated, and for several years taught in a Canadian high school. She was an industrious, capable, literary and ambitious woman. She died in 1867 at 67 years of age. Thomas Alva Edison was born Feb. 11, 1847, at Milan, Erie county, Ohio, but his parents removed to Port Huron, Mich., when he was seven years old, which has since been their home. Edison never went to school one day in his life. His mother taught him herself, and he was a remarkably apt scholar. He was a great reader, and fond of books from his boyhood. Edison acquired his love of reading from his mother. Among the books read by Thomas Edison in childhood were "Hume's History of England," "Gibbon's Rome," and several works of Shakespeare and Dickens. He also read the Bible through when a child, and to the conversation in the household he attributes his

MARVELLOUS MEMORY

which he now has. He was a precocious child. When a little boy he was a newsboy on the Grand Trunk Railroad, running between Detroit and Port Huron. He had a little basket in which he carried his wares for four years, surrendering it only when he was fifteen years old. He was then in the height of the "rebellion" though, but never had to wear the conscription uniform, even when he was of the proper age, for the reason that he was always too deaf. He attributes the origin of his deafness to scarlet fever when he was a child. He was also subject to earache at that time, and from violence and pains of an unusual character in the head. The beginning of an explanation, but a possible one, of his deafness is that he was, when a boy, accustomed to drive a horse attached to a heavy express wagon, and frequently came in contact with the rattle of the wheels, which, of course, would affect the hearing. He attributes his deafness to this cause.

His first attempt to generate a current was in the cellar of his father's residence, assisted by such aid. This failing, they soon after constructed a battery of 50 cells, which was successful, and a current was accomplished. About two months afterward, as the railroad train was leaving Mount Clemens station, on the 20th of July, 1862, Edison's father, the agent, the conductor, and a few others, crept aboard the train in front of the approaching car. Edison, standing on the platform, sprang into ground, seized the child and dragged it from the track. The conductor and the agent, who had witnessed the performance for the boy, volunteered to assist Edison

TO LEARN TELEGRAPHY.

Thereafter, on reaching the end of his route, he would hasten to the office, and practice on the key of the instrument. He was diligent and apt in operating. In the months he was thus employed he learned to be a fair operator, and in the autumn office at Port Huron. The office was in a country store, and Edison had an opportunity to indulge his mechanical inventions. He secured night and day for the instrument, and was thus able to work at night. The operators were required to report "all's" every half hour to the train dispatcher, and Edison, finding it frequently an undue task, when engaged in practice into all in the circumstances in such a manner that the report would be sent from the office call. This ingenuity was not discovered for a while, when it was discovered how he had been by the train dispatcher for an error, and Edison was discharged. He went to Stratford, Ont., where he had a number of relatives, remained there a few months, and then returned to Port Huron. He was now 17 years old, and had his situation brought to him at Stratford. He was appointed operator at Port Huron, and was very successful. He was successful financially, as he had saved considerable money, and was fond of reading and telegraphy. This is another without the qualities of a mechanical genius. He was constantly inventing, and "tried" everything that occurred to him. He engaged two rooms connecting together, and fitted up a laboratory, where he worked and experimented. Many of these experiments failed. When this was done he left the room in order, and no one was allowed to enter it. The "help" was also required to keep it in order. He was also in the habit of making experiments at night, and frequently remained there all night. He was also in the habit of making experiments in the office, and frequently remained there all night. He was also in the habit of making experiments in the office, and frequently remained there all night. He was also in the habit of making experiments in the office, and frequently remained there all night.

He had a "quiet personal friend," M. E. Adams, in the Boston office. An order was issued to work a heavy New York wire, during the absence of the regular operator. The wire was worked by "Dick and Ralph" both men, who, as a class, had the reputation of getting rid of work on the "Ralph Rattler," if possible. Edison, however, offered the situation to Adams, and the latter, who was a good operator, accepted. Edison, on account of his projected removal to his smooth work, and the next day was the first to report at the office. Edison was then appointed manager of the room, for the better employment of his time, and was required to keep a record of the messages sent. He placed some stamps on strips of tin-foil on the wall, and connected them with the wires from a battery. Whenever a message was sent he placed a punched hole on the tin-foil, and connected the wires. Edison's ingenuity was discovered, and he was discharged from one cell to the other, they were connected by a wire, and the operators, Edison stated a step in Boston

NEWBERRY, SOUTH CAROLINA, FRIDAY, APRIL 19, 1878.

Die Indiscretionen des Telephons.

Eine Geschichte aus dem Zeitalter des Telephons.

Das Telephon ist noch immer der Held des Tages.

Nach den jüngsten Ausländungen soll die neue Wissenschaft im besten Zuge sein, ein Mittel zu erfinden, um Ideen zu verpachten, Waare einzumachen, kurzum, daß eine im Jahre des Heiles 1878 gehaltene Rede nach Berlin erst im 1880, selbst in 1900, gehört werden könnte.

Das ist gewiß wunderbar, aber ich meine, daß unser menschenfreundliches Menschenmöglichstes ist an eine solche Methode gewöhnt, die bei Amerikanern Lebensnerven große Bestürzung hervorrufen möchte. Drum Sie sich die schrecklichen Folgen dieses Systems! Wie Einsiedler würde es, daß Jemand der Vergnügungssucht gegen die Zukunft aufzubrechen, Gesellschaften!

Ich sah in meinem Geiste die unglücklichen Menschen einer solchen reinsepsiotischen Telepathie worden sollen. Und schrecklich sind sie, sie könnte wir. Da ist z. B. Herr X., ein Wollterpolitiker. Er ist Candidat für ein Amt. Man hat ihn stark liberalen politischen Glaubensbekenntnissen damit sich das Zeitalter aufbewahrt. Jahre vergehen, der männliche Herr X. ist zu der Überzeugung gelangt, daß seine liberalen Gesinnungen seinen Interessen im Wege stehen, geschickt hat er umgesinnt.

Wie begegnen ihm auf der Rednerbühne einer politischen Versammlung, wo er einen alte Unsichten seine früheren Ueberzeugungen aufzuopfert und Phrasen schleppt, die seinen Principien als reactionärer Neophyt widersinnen werden.

Plötzlich läßt sich in einer Ecke des Saals ein Geräusch hören. Weich' merkwürdiges Geräusch. Man lauscht lagen, es ist das Echo der eigenen Stimme des Herrn X., welcher dort unbemerkt. Es sind in der That dieselben greulichen Worte, welche Redner-Dauf der Ueberzeugung. Nur . . . wie soll ich das Phänomen erklären? . . . Wenn der Ton auch bestehe, das Thema ist ein ganz anderes.

Und während Herr X. redet, regelt sich das teuflische Echo in weiteren Bahnen.

— Ja, meine Herren, sage der Redner, die sogenannten Freiheitsideen gefährden die öffentliche Ordnung.

— Nein, meine Herren, läßt sich die andere Stimme vernehmen, welche immer die feinige bleibt, lassen Sie sich nicht von den leisen Reden Derjenigen bestechen, welche behaupten, daß unser Land nicht für die Freiheit geschaffen sei!

— Mitnichten, meine Herren, fährt Herr X fort, Niemen sind diese sogenannten Reformen in der Verwaltung, mit denen man das Volk ködert.

— Stimmen, meine Herren, fährt gleichzeitig das schaffende Echo fort, Stimmen sind diese Zauberformeln, mit denen Gelüste nach den Portefeuille zu stemmen sucht.

Es hält nicht schwer, sich diese Scene unter geschulenen Geistern der Umwelzung ob dieses selbstsinnigen Antagonismus weiter auszumalen. Man sieht die Ursache davon.

Ein boshafter College hatte sich das gefährliche Vergnügen gemacht, in die Stimme einen alten telephonischen Apparat mitspielen zu lassen, in welchem die leise Sprache des Herrn X. alle er in den Reihen der Opposition sich, aufbewahrt war. Und jener unvollständige Duett eines einzigen Mannes war das Resultat.

Doch nun erst in der Diele.

Was für Verwirrung dieser darin das teuflische entsetzlichste Telephon stiften.

Das Gift spielt in einem Hausball, welcher seit zwei, drei oder vier Jahren je nach dem Zeitraumen der Zerstreitigen und der Zerfeindeten besteht.

Ein heftiger Zank ist ausgebrochen, man weiß sich arge Schimpfreden an den Kopf.

„Ach, wenn ich es weiter gewußt hätte," ruft Madame aus, „daß ich mein Leben an ein Ungeheuer gekettet, hab mich nur meinen Gedanken lieber gebeichtet!"

„Dein Gott! ich rühte dir, nicht davon zu sprechen. Du hast mich mit einer Mädchen im Walde angelacht."

„Du gefällst er also, Du hast mich nur aus eigennützigen Motiven geheirathet!"

„Einstoß Du, daß in dem Alter in welchem Du damals standest, noch pfiff und einander folgenden Verlobungen."

„. . . Er beleidigt mich, er beleidigt mich auf gemeine Weise! . . . Ihn betrete Gerichten zu eingehen und in der Erwartung, daß dort Gericht daß die Scheidung zwischen uns verfügen wird, flüchte ich mich zu meiner Mutter, mein Herr. . . Aber vorher will ich Sie mit den Worten Ihrer Geschwister confrontiren . . . Warten Sie einmal."

Darauf folgt Madame in ein aufgeschnob Gemach und holt einen kleinen, lichtgrünen Kasten heraus.

— Meine Freunde, sagt sie, Dank sei Gott, daß ich Sie gefunden habe, Sie retten mir meine Ehre, Sie allein, Sie allein, Sie allein . . . Ich spreche nicht zu den Männern, welche äußerer Rücksichten und der Vergnügungen wegen hier sind. Ich spreche zu Ihnen, Sie, Sie, Sie

suffered "to every amount," amongmany and about this time the boy left home to earn his own living. He had never been to school more than a few weeks, but he was enterprising and imitative, and he "picked up" a great deal and very fast. His business was that of a butcher, and when the war broke out, at fourteen, he became a newsboy on the railway. Stimulated by the eagerness of the public for news, he conceived the idea of printing their appetites for his papers, so he erected large bulletin-boards at the principal stations, and telegraphed the news headings of his papers in advance of the train. The result was a largely increased sale, and his plan was followed by others. This interested him in the telegraph, and he determined to make one himself. He strung a wire a mile long between his house and a neighbor's and constructed the instruments of iron, tin and wood;

but he was too poor to buy it, and they would not make one. So he obtained some cats one Sunday when he had leisure enough, he thought, to generate a current, and he fastened a wire to their legs and then massed up their backs, and waited for the result. The machine did not respond, and he blamed the rude instrument for his failure. "This incident," says his associate of many years, Mr. Edward H. Johnson, who relates it, "is perfectly characteristic of the man. He will to-day undertake elaborate experiments and conduct them with great care and marvellous patience and perseverance, although his person points to their utter futility. It is this trait, however, which led him into lines of original discovery and inventionunattempted by others."

While a newsboy Edison started a newspaper, editing, printing and selling it himself. He had a small press on the train, and on this he printed the little sheet, and he showed the most marked ability in obtaining a circulation of four hundred and fifty subscribers. A son of Robert Stephenson, connected with the Grand Trunk Road, sent back to England two hundred copies of Edison's "Herald"—the only newspaper in the world printed on a railroad train."

The boy now learned telegraphing, and rapidly attained proficiency, and occupied difficult and responsible positions. While at Cincinnati, when he was only twenty, he invented the important process of transmitting two messages over one wire simultaneously. Two years later he invented the duplex and printing telegraph which is at the basis of the Gold and Stock Exchange reporting instrument—the familiar "ticker." When he was at Boston he played an ingenious trick, which cost him his place. It was the rule for each night operator to telegraph to headquarters every half hour the number "0," and the name of the office, to demonstrate that he was wide awake. Edison contrived a machine which would, at regular intervals of half an hour, satisfy the central office without waiting him up, if he chose to sleep. He sold them to other operators, and was discovered, and "dismissed the service in disgrace."

It was about this time that inventing became a passion with him. He would work all night, and experiment with wires and batteries all day. This caused much confusion, for which he was occasionally reprimanded.

Edison is a tremendous worker. Work is a dissipation with him—his only bad habit. For the last ten years he has averaged eighteen hours a day at his desk. His home is within fifteen rods, but when he is in the crisis of an invention he does not go home for days, either to eat or sleep. He never went to school but a month in his life, but has taken out 157 inventions and filled 67 caveats, and is now only 31. Twenty-five men are employed in his laboratory merely to materialize his ideas. He is worth $150,000, and now has an income of nearly that every year.

Sunday, Oct 28

A beardless young man, of a pale, studious face, clear blue eyes, dreamy aspect, and chestnut locks —this is Edison, the inventor of the phonograph. He is very fast, and, it is said, has never heard clearly the voice of his invention. The phonograph is the 126th patent, and from his ingenious no is said to draw a large income. He has a bashful, quiet manner, but does not seem to enjoy society, and is rather so miserable as when he is alone. It is related that when in his city a few weeks ago, he spent three hours in an opera factory, and in that time he was introduced to only one of the little musicians performing, although he talked to quite a number.

ACADEMY OF SCIENCES.

PHONOGRAPH DAY.

A NEW VICE-PRESIDENT AND SECRETARY—A CHEAP METHOD OF FINDING THE SUN'S DISTANCE—THE PHONOGRAPH AND VARIOUS TELEPHONES EXHIBITED—HIS AGENCY MUCH ANIMES—HONORS TO MR. EDISON, AS INVENTOR.

[FROM A STAFF CORRESPONDENT OF THE TRIBUNE.]

The Academy met, April 15—The elections at the business session of the Academy attracted a notable share of attention. Professor O. C. Marsh was elected vice-president in place of Dr. Wolcott Gibbs, whose term of office had expired. It was deemed desirable to have the Secretary's address delivered during the evening, following the official heads of the Academy; hence this evening's session was all arranged in advance of mechanical adjustments. On this account Dr. Gibbs kindly urged the election of Professor Newcomb, as well as an increase in the terms of the new candidate. Professor J. W. C. Coffin (formerly superintendent of the Nautical Almanac Bureau), and of course a mathematician), takes the place of Professor J. D. Hilgard as Home Secretary—a circumstance which also furthered his view. Professor Marsh being Foreign Secretary of the Association for the advancement of Science, is now rapidly reaping the honors which have been justly his due; the Academy, in making him Vice-President, gets as much as it can for four. A verbal dispute, in the way of election within the past two or three days, the members felt the rioting from that kind of interesting combination. Consequently they did not add, as they were expected to, two more new members, to make the annual yearly addition of five. There is indeed a harrowing feeling among the friends of candidates, that the three elected yesterday are all who will be so honored this April. There are many of the other members who have not at all students to increase the number of membership, and a similar feeling is apt to be developed annually in the younger ones the day after they are elected.

MEASURING THE VELOCITY OF LIGHT.

The first scientific paper of the morning was by Professor Simon Newcomb, on "Plans for Measuring the Velocity of Light." He began by saying that he was communicating last results of determining the problem of the solar parallax—the distance of the sun. Among the most eloquent of the methods tried for this purpose was that which depended upon the speed of light. It is evident that if we know how many seconds it takes light to come from the sun to the earth, and we know how far it is from the sun in miles, we could at once calculate the distance of the sun by multiplying the two numbers together. Or, if we know the speed of light in miles, we can find the sun in miles by dividing the two numbers together. The former of two methods is pretty accurately determined by two independent methods, and the latter is the subject of the present discussion. Of the two methods the latter was perhaps the first to be suggested, and the finding by star light, travels in a second at certain approximate figure, but instead of caravan difficulty, devised a method by which the speed of light could be measured on the earth. The problem now to be attacked, is to send the light by means of a revolving mirror to a fixed mirror at a distance, and receive it back again on the revolving mirror from which it was sent. A new method of doing this has been devised, which seems to have been destined by an officer in the Navy; but on this the Professor Newcomb has as yet no particulars. The difficulty in the way of the method is the very limited character of the apparatus for such a long distance; hence, there is the chance of the light not being returned, the return ray, by which the velocity of light is measured, being too feeble. The method of Professor Cornu consists in the use of a crystal to produce the electric light alternately. The method of Professor Newcomb proposes to use

MR. EDISON ENTERTAINED.

Mr. Edison appeared somewhat overwhelmed by the attentions showered upon him at the banquet, but that this was merely shame, including a realization that Mr. Edison's work could not speak for itself. The phonograph and thermogen exhibited, and numerous associates, in the intimate atmosphere of the exhibition, succeeded in making the evening a most delightful one. Mr. Edison will remain with great discretion. Impromptu conversation was then held with Philadelphia, and all of the guests were introduced and responded briefly to the various telephones.

OXYGEN IN THE SUN.

When the Academy of Sciences met on Monday, Professor Henry Draper, of New-York, gave a report of progress in his experiments proving the presence of oxygen in the sun. Before Professor Draper made the discovery of that substance, it was supposed that the solar spectrum contained only black lines; he found a series of bright lines, which he has since identified as those of the oxygen. Photographs of the oxygen spectrum, with the solar spectrum alongside, of the same bright lines, were exhibited. To the twenty lines which he had previously identified he has since added ten, making the thirty best known lines of the gas.

Professor Draper gave a brief account of the difficulties of his experiments, and the ingenious means by which he had made them successful. One of the most curious of these contrivances is a "quartz compensator," which is used to correct the errors of the lens. The ordinary refracting substance, glass, is useless for spectral examinations, because it interferes by reason of its composition. He has sought for other substitutes in the sun; I think a thick crown of carbonic acid would be theoretically as yet almost useless. His most successful substitute is a lens of quartz, which he has used in the photographs of the oxygen spectrum that have shown the level of the photosphere. Professor Langley remarked that the photographs of the oxygen spectrum were the most beautiful he had ever seen. Dr. Peters on the solar parallax, discussing from historical and other data the evidences as to orbital calculations of the distance of the sun should be considered the most trustworthy.

Dear Doctor Agnew

LET THE EXHIBITION EXHIBIT.

Let us give a hint to the management of the Permanent Exhibition. Their programme for opening day, we very much fear, is not auspicious nor an augury of success. It was a fallacious idea to open on the first of May, along with and out of compliment to the great Exposition at Paris, but then the happy thought seems to have stopped. The programme, so far as developed, indicates nothing new; nothing attractive and nothing striking. It is, in fact, the conventional routine, worn and brass band of the village stage of municipal existence.

Now this kind of thing will not do in Philadelphia, or for any enterprise of the proportions and magnitude which the exhibition must assume to command success. An oration is simply a mechanical show-piece, and for such an occasion as this of the first of May utterly meaningless and inadmissible.

The Permanent Exhibition, if it is to be an institution, must move forward all the time. It must be on the wing. Stories of the past or on the work of the past, no matter how grand those memories are, how wonderful that work. It must gather as it goes, and sum up from year to year, and month to month, the record of all the progress of the world.

Since the closing of the Centennial Exposition there have been three great practical developments in the history of science, or, to speak more accurately perhaps, three great discoveries which have come down to the range of popular understanding. These are—

I. The Telephone.

II. The Phonograph.

III. The Electric Light.

If, on May 1, the people of Philadelphia, of Pennsylvania and of all the great cities of the United States, should know that in the old-main building of the great Exposition, all these three wonderful achievements of scientific discovery would be demonstrated and exhibited on a grand scale, not only the buildings but the grounds adjacent would be flooded and washed with a human sea. The present projection of the American mind is in the direction of scientific study and investigation. Popular science is the law of our people. Even technical scientific lectures crowd the Academy of the lecturer is a recognized authority, a Tyndal, a Huxley, or a Barker. How much greater would be the attraction of the brilliant demonstration which should embrace at one place and within the limits of one day the results of these three discoveries, which are dividing the eager thought and curiosity of the whole country. A telephone, or telephones, for popular use could easily be placed in each end of the great building three-fifths of a mile long. A phonograph, or series of phonographs, that never needed rest, from the cranks, might talk all day long in English, French, German, Spanish, Russian and Japanese, giving directions and information, to the surging throngs of strangers. The whole building could be easily flooded with the delightfully intensified moonlight of electric illumination. It is not too late to do this yet; ten days or five enough to switch in contractors altogether, and plenty of time to fit up an exhibition hall.

ANOTHER BENEFACTOR.

Dr. D'Unger, of Minneapolis, the Chemical Genius, Prospers Before the Days of the Centennial—He Cures Death Upon the Diabetic's Trembled Stomach.

[Chicago Tribune, April 11.]

In the issue of the *Tribune* of March 24 was printed the following important letter:

MINNEAPOLIS, Minn., March 21.—Editor Tribune: Can you have published numerous articles on the subject of diabetes, but none of them, so far as I have been able to discover, have resulted in relief to the sufferer. They were hopeless. With your permission, I will now give to the world, through the Tribune, a remedy that cures for diabetes—a cure that has been tested practically, and always successfully.

Let the invalid—I mention not whether he is bed-ridden, getting off, in beginning it, or on a tapper, or anywhere between—take a wine-glass of Dr. D'Unger's Diabetic Compound (Peruvian bark). This will cure any diabetes. Then, to not increase the dose to six glasses (teaspoonfuls) without any danger, and take it three times daily, one hour before a meal. It will create a healthy appetite for food. In the course of a few days the distressing symptoms of the diabetes begin to disappear, and in less not only all pain for the kidneys, but also the tendency to the way of disease.

Secondly, in this city, a well-known gentleman, who had been suffering not less than six months, and who was reduced to the verge of death by the various drenglists whom he had tried in vain for relief, and would recover, that he could almost see death; but they could hardly be called drenglists, for they were not, because, never before in the history of the world, did a remedy like this, and in the course of the first week I saw a change for the better. During the three months of his medicine for his own benefit, but the literature of medicine did not. Indeed, This case can be verified by the professors of nerves of our drug-stores. He will satisfied any one who will call on him. He will guarantee a cure in all cases, using this remedy alone.

E. D'UNGER, M. D.

In a subsequent letter communicated to the Chicago *Tribune*, Dr. D'Unger says:

As all medical men are doubtless aware, there is a large amount of admiration in the popular mind, and, consequently, banks which are blind with the greatest possessing that the curative power of medicine, but not the effective and certain properties which the genuine bark alone possesses. Quinine is a mineral, and we have, therefore, I should have mentioned that the bark out of which it is made *used to have*, for it is the most *terrible* property that exists in medicine.

It is a well-known fact that the doctor's remedy is a nostrum, and that he has ordered no prescription. The extract has also shown that it is not a nostrum, but a well-known compound, and the prescription is given in detail, so that any one can use it if he is careful to procure the right drugs. There have already appeared numerous lines in our columns attesting to the efficacy of Dr. D'Unger's cure, and we are pleased to observe one amusing at it, and another, that it is a "new" remedy for drunkenness. In the gospel temperance meetings at Farwell Hall the remedy is very much needed. It can be had in every town and city, sufficient quantity can be kept in a house. It is an excellent tonic, whether it cures intemperance or not. Chicago is full of people who ought to give it a fair test, and there is much sneering at it because it will work until it has been proved a failure.

If Dr. D'Unger has really discovered a specific that will cure diabetes of the terrible stage of insanity or dreaming death, he will be one of the greatest benefactors to the human race the world has ever known. If this remedy proves successful and possesses the wonderful curative properties that the writer of the above letter claims for it, he will be entitled to every man and woman who has an appetite for liquor, it would be a blessing to the world. If it will do this, it would do away with crime almost altogether. It would bring sunshine into that clouds of darkened homes. It would banish poverty. It would vanish crime and misery. It would make men industrious and economical happy. Any man who can bring about such results as these, has made a discovery that is the talk of which Mr. Edison's discovery is small. It may be that Dr. D'Unger's remedy is a specific for diabetes, but it is probably incorrect in this trial, and there are plenty of men in this city who ought to test it at once. There is no secret about the medicine or the formula. It is openly announced, and any one can prepare it. A very short time will test its merits. If it is found, the victim finds himself entirely free from it. He makes a brief struggle, but finally he has all the appearance of success. The meetings of the Farwell Hall sort in the city would be glad to give it a thorough test. A society free or small-pox, and it must be tested as that disease are. They, or those are open before the eyes of every abstruse philosopher on earth, whether or not the bald philosopher has learned that two straight lines cannot inclose a space. Appears, we are pleased that Mr. Thomas A. Edison, according to the only-written article in the Chicago *Tribune* by Mr. George H. Hiles, has been too busy with his inventions to elaborate a system of theology of his own,

for he simply believes that the existence of God can be proved in numberless ways, and on this simple truth his mind rests, meanwhile he gives his time to inventions that are of incalculable benefit to mankind. We must congratulate Mr. Edison on having a

Will The Man Who Thinks
That he knows it all please step forward?
Chicago is full of Editors known, and mid-wisdom, above the clouds, and Philadelphia is not behind her sister cities in the number of self-made, self-satisfied, self-opinionated gentlemen, who, if they would only deliver in the ranks, discourse with the Almighty Himself—day in, day out. Congress lives over $20,000 to one man ("Prof." Hayden) to complete the Tribune Statistical Encyclopedia is far off still feasible. What has the Government done for the discovery of the Phonograph, Telephone and Meters. Representatives, your constituents are making themselves heard. The time may come when the long among men will be recognized. "Behold him! It is he who discovered the hidden wealth and power of nature, grasped it, and made it serve humanity."

Let Congress follow suit from its example by generous and appreciative

Inventors, such a class, are modest. Being devoid of self-assertion, they are frequently left to struggle with poverty, and the world is the loser. Congress should sacrifice for material wealth. Would it not add to the honor and interest of the centennial celebration if Congress would endeavor to protect and encourage the inventor? Would it not be a fitting tribute to the memory of the inventor of the telephone (the inventor), ought they not to be rewarded? Congress appropriated $100,000 for the Centennial. Would a similar amount be too much for a phonograph, while a meritless, grasping corporation like the Bell Telephone Co. has been allowed to fatten on the profits for years, while the inventor, for lack of means, has been unable to defend his rights, and has been defrauded of his just dues.

The Telephone and Phonograph.—Professor T. A. Edison, with the speaking phonograph, made some practical exhibitions of skill at the Patent Office, before the commissioners and examiners, and then before the Senate Patent Committee and the House Patent Committee, attracting so much attention at the latter as to almost break up a quorum in the House. This evening he visited the White House by invitation. Quite a number of the members of both houses tested the machine, and were amazed to find their speeches reproduced with idiotic exactness. After the House had adjourned the phonograph was set on the Clerk's desk and told the amusing story of Jack and Gill so it could be plainly heard in all parts of the hall and galleries. Professor Edison received quite as ovation wherever he went. His reception by the Academy of Science, at which Professor Alexander Graham Bell, of the United Washington, was present in the president of the society to be so honored in the history of that body. He was introduced as the greatest living inventor of any country.

THE TELEPHONE AND PHONOGRAPH.

Professor Edison Exhibits His Wonderful Inventions at the Capitol.

The Telephone Transmits Speech Perfectly—The Phonograph Reproduces Sounds Exactly—The Talking-Phonograph Tests Its Responses.

Professor T. A. Edison, the inventor of the telephone, arrived in this city last night, and this morning he called at the Capitol and exhibited his wonderful invention to a number of members of the House and Senate. Professor Edison was accompanied by Mr. Edward H. Johnson, the general manager of the Edison Telephone Company, and Mr. Edward Gilliland, the electrician of the company. Professor Edison has been engaged for the past few months in perfecting his telephone and in bringing out his phonograph, and he has succeeded in both. The telephone is now in practical use in many cities, and the phonograph is now ready to be introduced to the public. Professor Edison has been in Europe for the past year, and has been received with the greatest honors by the scientific men of the old world. He was elected a member of the Academy of Sciences, and was also made a member of the Royal Society of London. He was also presented with the Albert medal by the Society of Arts, and was awarded the Rumford medal by the American Academy of Arts and Sciences. He was also presented with the Volta prize by the French government, and was made a member of the Legion of Honor. He was also presented with the Cross of Knighthood by the King of Italy. He was also presented with the Cross of Knighthood by the King of Italy. He was also presented with the Cross of Knighthood by the King of Italy.

THE PHONOGRAPH.

Edison's Latest Wonder.

An Evening with the Inventor in a Western Home.

It happened that Mrs. Barstingloue was going down to Keokuk for a few days, and Mr. Barstingloue was inconsolable. At one time he proposed that she should not go; he could not endure the lonesome house during her absence. And then again, he declared that if she must go, he would neglect his office, and he must always go to the house to see how, and he would go with her. At length, however, the persuaded him to be reasonable, and on her repeated assurance that she would not remain away longer than three days, he consented to let her go. He even brought her ticket, and ordered the carriage and paid for it two days ahead, last his resolution should give way and he should forbid her going from him. And from that time till the morning of her departure Mr. Barstingloue spoke in subdued tones, and moved about with the air of a man whose heart was buried under mountains of grief.

Before she left the house, Mrs. Barstingloue set the phonograph in the sitting room, behind the clock. Then she kissed her disconsolate husband, and began him to preserve his precious life for her sake while she was away, and then she was gone.

Every day, during her three days' visit in the Gate City, she received a letter from her mourning husband, hoping for a safe journey back and asking her how lonesome he was without her, and how he wrote the empty house echoed, and how he longed for her. And by his aching heart with tender feeling. He was the same house with sighs and heartier again.

The night after her return to Burlington, she took down the phonograph.

"Now, Barry," she said, "what we said last is for hearing? It must have been something while we were discussing my visit. Or may be it has caught some of your pet, longing mannings while I was away."

Mr. Barstingloue adjusted the crank.

"Then," resumed the phonograph, in tones of heavenly sweetness, "I shall go to-day to Mrs. Barstingloue's for three days; now for safe's sake, myself, this morning. Light your cigar while I fight about the house and make the room look deserted."

Mrs. Barstingloue exclaimed Mrs. Barstingloue, in a paroxysm of amazement, "what on earth is it saying?"

"Then," resumed the voice of your return home, I failed into it some time or other," replied her husband, nervously; "people will say such kinds of stuff into a phonograph, you know. They say it's fashionable."

And Mr. Barstingloue looking out of sound, gave the crank another turn.

"Then," resumed the phonograph, looking now as grave as the world as he had been when he was begging her not to go to Keokuk, "put it away; I hope you may have had no time to do so, and it might say something perfectly shocking, you know. Ha, ha, ha!"

And Mrs. Barstingloue, upon whom the spirit of investigation had descended with great power, looked at the phonograph, and she looked at her husband, and she looked at the phonograph, and she looked at her husband, and remembered.

"Barry," she said, "you've been stuffing that machine with your pet names, and you've been talking into it, and you've been—you've been—"

"Why, no, my love," said his wife, more dead than alive, "I've been talking into it, and I've been—"

The Post And Union.

THE POETRY OF THE PHONOGRAPH.

Its Harmless Feats and Capabilities—Is Humor and Solemnities.

The following extract from a report of Hon. S. S. Cox's late lecture on the Tenth Muse are too good to be anonymously recorded and. To layout valuable information in captivating periods is truly the highest eloquence:

"A treatment of the deaf and dumb is in keeping with a profit. He desires to converse with her. He exclaims: 'Come to me.' She smiled in the form of sounds. He makes an artificial ear. He breathes his deaf and dumb to talk, although they could not hear. He instructs them to divine thought by the motion of the lips. Melville Bell is the Ohio teacher. He is the discoverer of what he called 'visible speech.'" He taught how to use the mouth for sounds, which served as letters and words—a process by which sounds formed by six scores of various density and rapidity were transmitted to any distance by telegraphic circuit. Then follows the use of the voice, reproducing every word with care, ness; and we have the phonograph! Next comes the telephone, which borrows the sound.

These machines are wonders. The faster you turn the cylinder the higher the voice is pitched, and the more it is turned irregularly it will sing you a falsetto. By varying the velocity of the cylinder you make the voice a bass. When you reproduce tones by the electro-magnetism it is the human ear with its stretched membrane or diaphragm that is used. It is the tympanum sent on a distant flight by a metallic conductor. The idea of talking into a machine—as Mrs. Partington says—is absurd. But I have talked into it, and when it was put in motion (laughter) my own organism was not nearly so refined and delicate as this slip of metallic sheet. The drum of the ear, the auditory nerve—these are my nerve power, quick as the electric speech-beats. For and tongue are one and each, in the telephone, an improvement of the telegraph. If I say to you over the wire, 'Good afternoon my dear interest in this piece of poetic fiction,' you will be informed by the account given in the New York Tribune of the first words spoken into the instrument in the Memorial Hall-building at the Centennial Exhibition, and printed in a chaste paper. It gave an account of the 'Boston' invention. He read: 'Mr. Watson has arrived (Laughter.) Owing to the sibilants in the name, the letter s was omitted. Then the words were heard more distinctly. Mr. Bell began to converse with the assistant, and they were overheard by the second given in the New York Tribune of the first words spoken into the instrument in the Memorial

Phila Times Apr 25

THE DOINGS OF CONGRESS.

This country has felt wounding that the inventor of the phonograph has got his machine before Congress. A talking machine in Congress is nothing new, but it is something that the country doesn't need any more of, and, as the political conventions always remark in their resolutions, the phonograph in Washington will be viewed with alarm by everybody. And yet this new and truly wonderful machine may be as useful as it is dangerous, if handled with any sort of discretion. The correspondents will find it useful to set up in the house when executive sessions are in progress, or in committee rooms when the doors are closed on the public. The machine can be put under a desk and taken out afterward and a full report of the proceedings ground out of it. To Congressmen the phonograph will prove a great labor saver and do the work with much more exactness than the average statesman. No member can afford to be without at least one machine, and some members, as Hale and Spooner and Conger, can have their phonographic utterances stored to order by the wholesale, after the same pattern, without any particular manner of brains, but fixed to reel off words and words on the perpetual-motion principle. A rattle-box with a patent crank would make an economical sort of machine for this kind of member. But a good many phonographs of special talents would be required. Mr. Glover will want a machine adapted to the work of getting up in the House over blessed morning and making a personal explanation, and unless the fearless character of Mr. Glover's consultees is extraordinary he will have employment for a great number of these little instruments in the personal explanation department alone. Mr. Sam Cox will want a light and airy phonograph, nearly only a mustache, that he can fill with comic remarks and keep pointing at Mr. Ben Butler; it will be necessary to have this machine constructed with some fortification for defense, or at the very least to have some power to kick back when seized in its own hungries. Congressman Thompson will want one he can fill with a few select but profane and wicked things in Pennsylvania, when there is plenty of room for something of that kind at this particular time, goodness knows! Mr. While needs a phonograph mounted on a rather active pair of legs to move around newspaper row and tell the correspondents all about it; Senator Don Cameron may attempt his to secretest notes that shall float out on spring breezes laden with the perfume of pop blossoms, for there—

[Inventor Wade Owen the full heart reveal
The presence of the how it would sound.

Mr. John I. Mitchell can put his phonograph under his arm, and going up to the White House jog in the evening Sunday evening and converse; Pennsylvania would be in search of a machine which never said anything intelligence in the matter of the draw, and there are quite a number of other members who will want about it to pass in the Senate, where they do many to see that a few objections will give the country fewer words, and they may as well begin. Senator Conkling will want a machine that will say "I resign my seat," and Senator Platt will want one for Senator Morton that will say "I am not dead," and Senator Dorsey will demand a kind that can make suspicious postal contracts and not get found out. Senator Bill Russell Smith must on instrument that he can set up behind the door when he wants to communicate with—Garfield, for instance; Senator Kellogg's phonograph will have to understand the noble virtues of the Returning Board cured—something not within human understanding—and grief out its praises and work to get ofice Federal offices for it while honest people sleep; General Butler will probably fill his with bricks and fractional currency and Democratic veterans of ten wars and such loose articles, and when these things begin to fly around the House all other phonographs will have occasion to get out of the way. There will be an overwhelming demand for a common kind of phonograph that can make a tair stump speech full of expressions of love for the people, to circulate in the various Congressional districts. It won't be much trouble for the inventor to get up a machine of this kind, needing only care to see that it isn't too intelligent, in which event the people would just as likely as not want to have their law making done by phonograph without the expensive trifling of human beings in the transparent disguise of statesmen. Anybody can see that the phonograph will have its uses even in Congress, but these ought to be a limit to the number.

Anybody can see that the phonograph will have its uses even in Congress, but these ought to be a limit to the number.

THE RIVER AND HARBOR BILL—A DISCUSSION WHICH REVEALS THE BAD FEATURES OF THE MEASURE.

The House spent a useful and accurating day over the present against the River and Harbor bill. The discussion, as usual in such cases, took a wide range, and the bill, when has passed the House, will probably remain in the Senate through the expensive months of a law only of the last business today. Mr. Cockrell, of Kentucky, remarked that in house one of the rivers proposed to be "improved," and that the only way to improve it was to demolish it. Mr. Wright, of Pennsylvania, knew two of the stone rivers and told the house that their sentiment never was about enough to drive one herdsman stood great distance on a dry day. Mr. Kelley, of West Virginia, was one of the members of the bill, confessed that the committee under his leadership had uttered new surveys whenever members desired them, without [illegible] Mr. Kelley, several members, representing Messrs. Reed, Hewitt and Hamilton, presented against the bill, and Mr. Wright, without distinction of politics, Mr. Randall, Wright, of Pennsylvania, who is sometimes to vote in favor of such appropriations as interest his own district, and Mr. Reed, said he would vote a great if $150,000,000 of $10,000,000 for proper objects, but he would not support the bill, which goes money for improper objects and for the benefit of such a man as Jones. Kinney was no other point than the house must decide whether a present by Congress was a privilege matter, but by time the real purpose of the present necessity, to have their present representatives in the last interest of the bill, was attained, it is probable that time is the last River and Harbor bill that will be passed by the present Congress.

A POLITICAL CONUNDRUM BY A REPUBLICAN ORGAN.

The political papers here were stamped all day and evening in an effort to unravel a mysterious conundrum which appeared tantalizingly in the political news of the morning papers upon the morning. The conundrum was printed as it is in the original form of the story. The inscription on the piece read:

WILLIAM ORTON,
Died at Geneva,
April 27 1878.

At the head rested several beautiful sentiments and a floral arrangement of blue violets, white roses, and immortelles. Next silver, the gift of the triangular Association, of which the deceased was a member, and a cross two feet in length. The cross was also filled with fragrant flowers, and standing in the centre of the floral arrangement. Next was a magnificent floral piece, composed entirely of flowers, the gift of the mercantile house of Orton Brothers. The piece was in the form of a wreath by banging over and partly hiding the casket, two exotics, the portions of which filled the entire space.

Next in magnificence was the floral arrangement on either side of the two central pieces were accepted by the Geneva Lodge of Masons, of which the deceased was a member. It consisted of a floral triangle and compass, surrounded by the letters G. L. Next was a floral piece, the gift of the Geneva Lodge of Odd Fellows, of which the deceased was also a member. It was composed of white flowers, and standing in the centre of the floral arrangement was a broken column, with the letters I. O. O. F. on the front. Next was a floral piece, the gift of the Geneva Lodge of Elks, of which the deceased was also a member. It was composed of white flowers, and standing in the centre of the floral arrangement was a broken column, with the letters I. O. O. F. on the front. Next was a floral piece, the gift of the Geneva Lodge of Elks, of which the deceased was also a member. It was composed of white flowers, and standing in the centre of the floral arrangement was a broken column, with the letters I. O. O. F. on the front.

WILLIAM ORTON'S FUNERAL.

DISTINGUISHED PERSONS PRESENT—THE THE MANY CONTRIBUTIONS TO THE BEAUTIFUL.

[From our Fourth Edition of Yesterday.]

The Church of the Holy Apostles, at the corner of Twenty-eighth street and Ninth avenue, was densely crowded with the relatives and friends of the late William Orton, owing to the funeral services this day. Long prior to the arrival of the funeral carriages from the residence of the deceased, where brief services had been held at ten o'clock, distinguished persons began to arrive at the church. They were for the most part gentlemen, and were followed by two ladies dressed in black, who engaged seats to those who were known to them.

Among those present were Mr. Thurlow Weed, Judge John Davis, William H. Vanderbilt, Cornelius Vanderbilt, Jr., Hamilton Mckay Twombly, Chauncey M. Depew, General Sickles, several members of the Legislature, Thomas Conigan, Colonel Cockcroft, Mr. Bowen, Mr. Bell, Mr. Hamilton, Mr. Gilbert, and the proprietors of the Times, Tribune and Herald, Messrs. Reid, Jones, Hoe, Pulitzer, and Gallagher. Among the ladies present were Mrs. Twombly, Mrs. Depew, Mrs. Pulitzer, Mrs. Gallagher, and Mrs. Hoe. Numerous telegrams and letters of condolence were received by Mr. Orton and his family, and a committee from the Union League Club composed of Messrs. Horace Porter, Cornelius Vanderbilt, Jr., Chauncey M. Depew, Edward Cooper, Hamilton Fish, Jr., Samuel Sloan, Jr., Samuel Sinclair, Samuel Thomas, Lieutenant Governor and David Dows. The Secretary of the Western Union Telegraph Company were present during the services. The floral offerings were very beautiful and appropriate, and were in the nature of this and various other orders. Near them stood a magnificent floral piece, the gift of the Union League Club of New York City, of which the deceased was a member, and which was received by the Rev. Dr. Morgan Dix, Rector of Trinity Church, and Mr. Bowen, Mr. Bell, Mr. Hamilton, Mr. Gilbert, Mr. Sloan, Mr. B. H. Bristow, Mr. Cornelius Vanderbilt, Jr., Mr. Depew, Mr. Cockcroft, Mr. Conigan, Mr. Sickles, Mr. Weed, Mr. Davis, and Mr. Vanderbilt. As they slowly passed down the aisle the choir chanted the solemn words of the burial service appointed for the occasion. The casket, which was of rosewood covered with dark cloth, with silver handles, was borne by the pall-bearers, who were followed by the relatives and friends in front of the altar. The inscription on the plate read:

WILLIAM ORTON,
Died at Geneva,
April 27 1878.

At the head rested several beautiful sentiments and a floral arrangement of blue violets, white roses, and immortelles. Next silver, the gift of the triangular Association, of which the deceased was a member, and a cross two feet in length. The cross was also filled with fragrant flowers, and standing in the centre of the floral arrangement. Next was a magnificent floral piece, composed entirely of flowers, the gift of the mercantile house of Orton Brothers. The piece was in the form of a wreath by banging over and partly hiding the casket, two exotics, the portions of which filled the entire space.

Next in magnificence was the floral arrangement on either side of the two central pieces were accepted by the Geneva Lodge of Masons, of which the deceased was a member. It consisted of a floral triangle and compass, surrounded by the letters G. L. Next was a floral piece, the gift of the Geneva Lodge of Odd Fellows, of which the deceased was also a member. It was composed of white flowers, and standing in the centre of the floral arrangement was a broken column, with the letters I. O. O. F. on the front. Next was a floral piece, the gift of the Geneva Lodge of Elks, of which the deceased was also a member. It was composed of white flowers, and standing in the centre of the floral arrangement was a broken column, with the letters I. O. O. F. on the front. Next was a floral piece, the gift of the Geneva Lodge of Elks, of which the deceased was also a member. It was composed of white flowers, and standing in the centre of the floral arrangement was a broken column, with the letters I. O. O. F. on the front.

THE EVENING STAR.
WASHINGTON,
THURSDAY.....April 18, 1878.

The National Academy of Sciences.

SCIENTIFIC MEMOIRS.

The first paper read at the scientific session of the National Academy of Sciences yesterday was by Prof. Asaph Hall, entitled "Preparatory Report in the Deep Sea Soundings under the United States Coast Survey Steamer Bache, during the past winter, in the Gulf of Mexico." It was a brief but very interesting account of the methods employed in the dredging and sounding operations, and of the results obtained. The depths sounded were eighty hundred miles. The temperature rapidly and certainly with which sounding was made, and also at the bottom. Specimens of the sea-bottom were obtained for examination. The paper was accompanied by charts, showing the lines of soundings, and by the specimens themselves.

Prof. Agassiz, who, by his desire, read his paper without notes, framed his remarks to a large extent upon the work of the steamer Bache. He expressed his pride in the fact that it was discovered by Professor George Davidson that the Japan current struck the coast of California miles to the northward of where it was supposed to strike. Upon the bottom of the Gulf Stream, Prof. Agassiz said, he found a great deal of the Globigerina ooze, which was first discovered by Prof. Wyville Thomson, and described by him. Prof. Agassiz also found the Globigerina ooze in the Caribbean sea, and in the Gulf of Mexico. He found it in the deepest soundings, and also in the shallowest. He found it in the Florida reefs, and in the Bahama channel. He found it in the Gulf Stream, and in the Florida current. He found it in the Florida current, and in the Florida channel. He found it in the Florida channel, and in the Florida reefs. He found it in the Florida reefs, and in the Bahama channel. He found it in the Bahama channel, and in the Gulf Stream

WASHINGTON LETTER.

Curiosities of the Dead-Letter Office—Night Seeing and Star Gazing—The last Card of the Monopolists and a Trump.

From an Occasional Correspondent of the Boston Journal.

In my last letter I briefly alluded to the postal system of the United States—how it had grown up in a hundred years from a few letters posted in all the country in saddle-bags, to a most wonderful, omnipresent, complicated but ever acting screw, whose operation brought manifold blessings to forty-five millions of people. But the most curious part of the work assigned to the postal machinery is that which it fails to perform. Those failures, however, must be charged to the people, and not to the mail carriers. If you wish to see how many ridiculous mistakes and blunders people can be guilty of, there is no better place to study this subject than in

THE DEAD LETTER OFFICE.

Here come every day thousands of letters, packages and postal cards from all parts of the United States, which have by some means or other missed reaching the persons for whom they were intended. There are thrown in huge piles upon tables, and a score or more of clerks deftly open the stray missives that have come back because they could find no owners. The cause of going astray is frequently made apparent by slight examination. Directions illegible has more to do in the matter of mistakes than anything else. One man forgets to put a stamp on his letter, and the only way to secure this omission is to send the letter to the P. O. D. at Washington, where it is opened and returned to the writer. Another man writes his own name instead of his friend's on the superscription, and, after wandering thousands of miles, like a lost spirit, it finally gets back to him through the Dead Letter Office. Another forgets to write any direction at all, and the poor whitefaced envelope must assume the responsibility of a traitor to the general receipt-file for all stray mails. Still another directs his letter to "John Smith, New York City." As there are several hundred of this distinguished name in the great American metropolis—one or more in every ward's block—the letter is opened and examined by score of John Smiths, and after many visitors to Washington, and chance look to the writer, it is the rule of the Dead-Letter Office to return to writers all letters of any possible value, where the name of the writer appears. This does not always appear, however; and still more frequently is so badly written as to make it impossible to do anything more than attempt to imitate an ugly scrawl on the returning envelope. The queer things embraced in the vast or colossus of these vagrant epistles must fully satiate the curiosity of the lady clerks who operate in this department. If Madame Eve had been in a good letter it is doubtful whether she would have ever attempted to seek forbidden knowledge by eating forbidden fruit.

Outside of the letters, however, there is an immense number of strange and curious things that find their way to the Dead-Letter Office, and as these cannot be returned to the senders, they are sold. Irony time to time at public auction. There has lately been an auction sale of this kind, the printed catalogue of which embraced nearly ten thousand different packages. These immense omnium gatherum embraced enough to stock several provincial clothing, jewelry and notion stores, besides a large curiosity shop. Here are a few sample bricks from the collection. One dozen smoked herring; one whetstone; one bar lunge, bologna sausage, loaves of bread, crackers, cheese, &c., six lamp mats, birds' wings, flags, small saws, pocket-books, stockings, garters, false hair, tooth brushes, knives, purses, pictures, bed spreads, underwear, slippers, toy engines, shoes, carved pipe, dice, chemise, playing cards, pills, corsets, fox skin, comforter, bass bells, cartridges, molders' tools; one knife, one stove, one bugs, buttons, yarn, books, watch-crystals, lamps, looking-glasses, leather apron, sheets, cameras, revolvers, ammunition, telegraphic instruments, music skin, bear skin, strawberries, condensed milk, horse powder, untanned lure, wax flowers, mathematical instruments, glass ornaments, lunar, saw, mill saw, hammer, dagger, centiped and tarantula in liquid, life preserver, billiard balls, five boxes of snuff, bustles, weights, scales, specimens of opium, &c.

SIGHT-SEEING AND STAR-GAZING.

Last night I went with Rev. Dr. Wilde and my friend Colonel Gustin, of Georgia, upon a pleasant invitation from Prof. Hall, of the National Observatory, to have a peep at the moon through the monstrous telescope. This is the largest, and probably, the best, instrument of the kind in the world. The best of all is it of home manufacture, having been completed by the Messrs. Clark, the famous instrument-makers. This telescope is a refractor with an object glass twenty-six inches in diameter and more than twenty-two feet focal distance. The view of the lunar mountains was most satisfactory, as well as of some double stars. Prof. Hall has immortalized both the instrument and himself by doing it up discover the two moons of Mars, and has heartily glad that a man so favored in the heavenly science of astronomy, and so dignified for his modesty and urbanity, should have made the grandest celestial discovery in the nineteenth century.

I have just now returned from a room of the Senate Committee on Patents, where I met for the first time Mr. Thos. A. Edison, the great inventor of the age. The room was crowded with a hundred or more, including Senators, scientists, ladies and others, and Mr. Edison gave a most satisfactory exhibition of that modern miracle, the phonograph, or talking machine. This instrument has already been described in almost every newspaper of the country, and I shall not attempt a repetition. It preserves and repeats articulate sounds, and variously every word and every tone of voice used by the speaker. In the present instance it produced in the hearing of the company a great variety of words and sounds. The whole repertoire of barn-yard music, from the cooing of a dove to the quacking of ducks, tackling of hens, crowing of cocks and lowing of cows. Then it repeated sentences of common music and into the mouth-piece; also Yankee Doodle, Dixie, Old John Brown and other popular airs. Then it would burst out in strains of poetry, such as "Bigger on the Table," "Mandalay," Old Mother Hubbard, Jack and Jill, &c. Then whistling, laughing, crying, shouting and singing, by turns.

"Mary had a little lamb,
Its fleece was white as snow,
And everywhere that Mary went,
The lamb was sure to go."

This, and scores of other bits of talk or poetry, were given with amazing accuracy and distinctness. Mr. Edison, like every great man, is a most modest, unassuming gentleman, but possesses a wonderful genius as an inventor. He has taken out in the last few years 150 patents and seventy-five caveats, and in the last year upon the threshold of his life's work, FIFTY-FIVE.

THE LAST CARD OF THE PACIFIC MONOPOLISTS.

Congress has not made any great progress in legislation during the past week, but the committees generally have been hard at work.

In the House Committee on Pacific Railroads an effort was made by the attorney of some French holder of bonds issued by the Memphis & El Paso Railroad, to invalidate the title of the Texas & Pacific Railroad, Messrs. Scott, Brown, Vice-President of the Southern Pacific road, proved to the satisfaction of the committee the perfect validity of his road to all it claims. This comes to nought, and the combined Southern opposition to the T. & P. to the California railroad syndicate only increases the strength of the measure which they wish to defeat. Men that were doubtful now mostly see the

CLOCKS WHICH WILL TALK.

THE WONDERFUL POSSIBILITIES OF EDISON'S INVENTION.

How Letters may be Dictated, Books Read, Songs Sung, Bells Made to Strike Hours, and Cry—All Through the New Phonograph.

Mr. Edison's Office Crowded for Half the Day.

Of all the writer's inventions, none has commanded such profound and eager attention throughout the civilized world as has the phonograph. This fact manifests properly to that peculiarity of the invention which brings its possibilities within reach of the specialist's imaginations of all thinking people, as well as to the almost universal applicability of the foundation principle, namely, the retaining by and recalling of sounds hitherto fugitive and their reproduction at will.

From the very abundance of conjectural and prophetic opinions which have been discriminated of the press, the public is liable to become confused, and less accurately informed as to the tremendous boon and absolute novelty which that the invention had been one month ago. Until a specific application, or line of applications, is made, the public is liable to lose interest in the matter. The fact that the invention is not perfected at the moment of its announcement, but that it is only in the line of future improvements, is liable to create a feeling of indifference. Yesterday the writer had an interesting one, and seems to us well worth being followed out.—Ed. [Ed.

N.Y. Herald Aug 28

The Future of the Phonograph.

"A highly interesting article on the phonograph, written by Mr. Edison, the inventor of this latest mechanical marvel, is published in the *North American Review*. We reprint to-day selections from this article, which derive their value from the source of the information they impart. Of the future of the phonograph its inventor confesses himself unable to speak positively, because its application cannot be defined like that of an instrument, intended to fulfil specific purposes, like a clock, a sewing machine, or a reaper. The range of application of the phonograph seems unlimited, because the mechanical difficulties to be overcome are reduced to a minimum by the simplicity of its mechanism, and it is not dependent on the operation of forces other than purely mechanical. Yet Mr. Edison has sketched for us a description of the uses to which the phonograph can be put immediately and without any further improvement, developments of his powers. Basing his statements on the fact that the phonograph captivates fugitive sounds and imprisons them for unlimited reproduction, inventor of their source of origin, he declares that the instrument can be used for letter phonographic writing, by which the recorded sounds can be transmitted through the mails and reproduced as often as desired at distant places. It is, as it were, a mechanical letter reader operated by clockwork. The recipient of the letter sits at his desk and the instrument reads his correspondence for him in a clearer and much more accurate and perhaps than a clerk could do it. In like manner phonographic books can be prepared and the instrument can read literature aloud to a public hall or school room for the benefit of large audiences. Music can be repeated in the same manner, and the cries, calls, &c., used for business advertising, uttered in sonorous tones by a tireless, limpless piece of machinery. The surprising accuracy of the record of sounds is proved by their reproduction. It is to there proven that the marvellous simplicity of the phonograph strikes the observer and learner. The children of the future will be educated in a manner that can be at once entertaining and instructive, for speaking toys will become as common as the squeaking dolls and dogs of to-day. In combination with the perfected telephone the phonograph promises to revolutionize the present system of telegraphy. It will be no longer necessary to write messages for a telegraph operator to read and transmit. They can be spoken and heard only by the sender and receiver, who are interested. As the steam engine and the telegraph have been the great engines of this century one of those of the next will undoubtedly be the phonograph.

N.Y. Herald Aug 28

EDISON'S WONDER.

The Phonograph and Its Application Described by Its Inventor.

GREAT POSSIBILITIES.

Fugitive Sounds Captured and Imprisoned in Tin Foil Sheets.

TELEGRAPHY REVOLUTIONIZED.

From an authority so worthy of attention as the inventor himself we learn of the many agreeable as well as useful purposes to which the phonograph, or talking machine, can be put. Under the title "The Phonograph and Its Future," Mr. Edison publishes an article in the *North American Review* for September, in which he depicts the marvellous results that will ensue from his experiments when developed by invention, and points out the manner in which the new instrument is adapted, and in many instances more convenient, than the telegraph, the writer, speaker and singer. Its usefulness is also seen in the near future a complete revolution will be accomplished in our every day habits in the way work of bookkeeping, and that, hyperbolic reverse of the literary structure of man can be secured and reproduced as often and in as many places and countries as desired. It is with the view of setting accomplished experience at rest that the inventor of the phonograph gives his own description of the instrument to the public. He says:—"From the very abundance of ascertained and prospective successes which have been disseminated by the press the public is liable to become confused and has accurately intimated as to the immediate reach and extent of the phonograph than if the invention had been now confined to certain specific applications, and the interest of new interest to its means." "And with regard to the possibilities of the application of the phonograph to such purposes as the reproduction of the letters and words of the phonograph it is practically applicable to almost any, for instance, for a trifle may extend almost indefinitely."

WHAT HAS BEEN ACCOMPLISHED.

The success already achieved by Mr. Edison in this connection up to the present time is extraordinary, and the following statement will show the gratifying manner in which the inventor has succeeded in his experiments:

"A perfect machine which shall correctly represent the speaker's voice in all its variety—its articulation, its pitch and other sound waves."

"A machine which shall reproduce from two to one hundred copies of any original record."

"A machine which shall reproduce any record with sufficient clearness and distinctness to enable a person to understand readily the words spoken into the apparatus when they were new process. The only perceptible loss will be in the quality of the voice—a loss inappreciable in the practical application of the apparatus."

"A machine which shall reproduce any record with sufficient accuracy as to the pitch of the voice to enable a person to recognize the voice of the speaker when the record is reproduced

THE DAILY GRAPHIC

FRIDAY, APRIL 26, 1878.

A REACHING RECOMMENDED.

UNCLE SAM—Gentlemen, a notice pointing a-h, to the door and observes you are-dy. What are-y waiting to be out? Is it—Cork? No, but call I do for you?

Enter Uncle Sam and Messrs. Green and not yet so green to Fleecy. We come in to enquire their size.

UNCLE SAM (to MCLAC)—Well, sam, what do you know about it?

MCLAC—Why, Sir—Sam, they seem a big piece of property and they look unobserved.

UNCLE SAM—How do you know?

MCLAC—I see 'em on-ly, per house, right facing me opes.

UNCLE SAM—Why didn't you prevent it, sir gave an alarm?

MCLAC—Sir, I was with 'em. I didn't mean to state, Sir, that I was in the house accidentally unobserved.

UNCLE SAM—The servants follow the other thieves away off the plantation, I suppose?

MCLAC—Yes; I did it all by myself; I was unmarried.

UNCLE SAM—Well, where is the property now? What did you do with it?

MCLAC—Sure, I carried it off and gave it to Bad Harvey, He's a frind'on it now this minnetes—the explosive and thafe of the woodst I was unmarried.

UNCLE SAM—Bimmerised!" Well, you haven't been bamboozled! Impossible—all those two years, and not a single—

MCLAC—No, Sahib; I his tryin' every day to get some of the stolen property back.

UNCLE SAM—For pay?

MCLAC—No, for me.

UNCLE SAM—Ohe! That's it, is it?

MCLAC—Sing, all the worse thing.

UNCLE SAM—Did he promise to give you a part of the stolen goods?

MCLAC—Faith, no sir, or a frind of his did. He said if I'd do all the rissin' he'd give me some of the best an'ver House—It's the truth I'm tellin'—Uncle Sam—I'm a hapenin-ded just a sight of it. That's thrue.

UNCLE SAM—Then you're an accomplice that you approximated—

MCLAC—What's that, yer riverince?

UNCLE SAM—Split the goods—you say you stole them yourself.

MCLAC—The saints preserve me, I'ish '—no, I was not interested, yer H ...ce.

UNCLE SAM—And if the Bad Harpe you speak of had given back a part of the goods, would you have seen him?

MCLAC—Wud a big ass accuse, yer Honor?

UNCLE SAM—Ass, in that case, you couldn't have been acquiring about the robbery?

MCLAC—Sure, I wouldn't. Who should I per House?

UNCLE SAM—Then it is because you didn't get any benefit from the robbery that you exposed the Harpes?

MCLAC—Why, yer Honor, long life to you! I stole some of 'em myself, and some other fellers, for I took me this feller wanted, and not a cint has he ever gin me for it.

UNCLE SAM—How came you to do such a wicked thing?

MCLAC—I was interested.

UNCLE SAM—And if you didn't either of you know that you had done anything wrong till you found that there was to be a fair divide?

HARVEY—Yis, Sir, yer honor; we're awfully chated, and we is very sorry, and have been fairminded enough to own for an honest treat!

At this juncture Uncle Sam stamped, and the prisoners, who had unobserved drawn near during the ...covery of moral sentence, and moved, ...strology." The dogs and the two honest fellowers started simultaneously for the front gate and made a reach of open country beyond. Uncle Sam smiled blandly, and went in to continue his experiments with the photograph. And as he turned from this moral cylinder, it said: "Ha! Ha! Ha! Ha! Ha! he is a liar."

A Photograph at Niles.

Niles, April 25.—The process of making the asphalt pipe which we use here, requires machines which have a cylinder equal in diameter to the pipe to match, and which revolves very slowly. An idea entered the head of a certain person to attempt a photograph, which was carried into effect. A sheet of heavy sifted paper which is used to prevent the asphalt from sticking, was carefully placed around one of the cylinders, and a cone made of tin with a diaphragm made of very thin sheet brass with a point soldered to its center was attached as to travel slowly from one end of the cylinder to the other, so that both being in motion a spiral line was projected on the paper. The parties trying it were all quite elated, but after running a few turns ...using the cone to what seemed to be a best position, the points made plain and distinct impressions, and by turning the cylinder back the sounds spoken were, to our surprise of all, plainly repeated in a strange muffled sound like a person speaking under bed-clothes or shut up in a closet. The experiment seems likely to prove a success, means were taken to get a number of visitors to come and see the operation of making the pipes. They are being informed that a phonograph was receiving all that was said. In the evening an enlisted few went to the shop, locked the doors, and reversed the motion. Back to our ears came a babel of sound that was indescribably ridiculous such as: "Mose soap," (the lachrymose term for hot asphalt) this very loud, "Oh, what a many sweet," "Hold up your dress, Cynthia out of the way," "—the ...ers are in ——'s the drivers?" "Here soak," "Where's the doctor, isn't he sweet?" "Oh, there's the man that sings in the choir," "More soap," "There's a pretty girl," "Don't bring that rosin ...to——" etc.

BORN FACTS ABOUT MODOC.

[*From the Boston Herald.*]

While coming to Detroit he became acquainted with the electric operators and learned telegraphing. His newspaper leading to extensive acquaintance of the train. He became impressed with the wonderful ingenuity and determined to learn the business. He ...ed Modoc was on the electric telegraph and, in ...ntelligence with an operator in his own town, ...ed him to learn telegraphy and he soon acquired ...ficiency to read the dots and dashes. He then ...ained with instructed with intelligence ...ed to receive over the wires. He was ...ed to receive ...ssages from the Detroit office at the rate of ...ty words per minute. This was considered ...ood speed for those times. The first message he ever received was from a friend in Detroit, and was ...ollows: "Modoc, you are a liar." He was ...ed at first, but, upon reflection, he could ...ink of nothing wrong in the message, and ...ed it to mean that there was a mistake in the ...ssage. He then sent the message back to the ...ce from which it came, and received the reply, ...ed: "Modoc, you are a liar." He was ...ed at this

The Phonograph

In reference to Prof. Mayer's account and Prof. Fleming Jenkin's letters, I may say that I had an opportunity of Mr. Isenor's observation of a phonograph constructed by Mr. Stroh, 432a, Hampstead Road, on April 3, at the invitation of Prof. Graham Bell. The difference between words produced from the phonograph and those spoken into it, gave me the impression of a difference between a worn print and an embryonic of no engraving. When the words were uttered loudly and slowly by real voice rather faster, it was easy to catch the sense and meaning, but I doubt whether unknown English words would be recognised, and certainly unknown foreign words would present insuperable difficulties. I should myself feel the phonograph of engraving pronunciation, especially delicate shades of distinct utterance. Some words, as *ee, oo*, almost disappear, *sh, ch, s* are difficult words, so that Prof. Bell at first thought that the first sounded like the second, while in reality both are altered to half-shut sounds that I do not remember to have heard in speech. The resemblance is great, however, that *Ada, Anna* could not be distinguished, though two cards neatly with *a* and the other neatly with *oo*, and their only other difference in its *oo, ds* in *Sea, Send*, are really the only good ones. Hence I feel quality by altering the rapidity of rotation and therefore pitch. As far as I could observe the quality did change, as it does in good sounds, but as might be expected—even when the effects were recognisable, they were not always true. Thus, *Anna, mother, pencil master*, fat *mates* failed. The instrument is, however, not delicate enough for being out these differences. The mechanical obstacle of the tin-foil, which has to be interval, and offers too much resistance, seems to be the cause of it. Such a word as "no, when sung rapidly, at the beginning of *Scots wha hae*, degenerated almost into the simple vowel, the

initial and final *s* were quite lost, and the action of the mute *c, t*, was almost nil.

The invention is highly interesting, the effects at present produced are sometimes startling (as it cries, coughs, laughter passion of a very complex compound character, and using it as a model to reproduce that vibration) is exceedingly attractive, differing in many respects from the one described by Prof. Mayer—has not been beyond a lecture illustration or a philosophical toy.

ALEXANDER J. ELLIS

April 13

Country Journal: Michigan

—We have written on to Edison for five phonographs. When we get them we will talk our editorials to them, thus saving the time and trouble of writing. Then when they are finished we will set them up over the printer's cases with a treadle attached to each so that the printers, with their feet, can regulate their to show off the words and whatever them in their own just as fast as wanted. Then the compositor's ears will take in his copy and their eyes will only have to watch the type. We expect Edison to give us two machines for suggesting this new use for them.

EDISON:

An Interview with the Great Inventor of Electrical Machines.

From the New York Graphic.

We went over to Menlo, N.J., two days ago, to see Edison and his wonderful inventions and make some discoveries and sketches for the *Graphic*. Menlo Park is not a park. It is not a city. It is not a town. It is not in any way related to Mungo Park, the great Scotch African. Although it is on the Pennsylvania Rail-road (just beyond Rahway), it is not even a stopping place, except when the agent flags the train to take on waiting passengers. It is composed wholly of Edison's laboratory and half a dozen houses where his employes live. It is, in short, Edisonia, and nothing else.

Just north of the track is a long, plain, white wooden building, full of windows and two stories high; this is the laboratory of the Newer Columbus whose name has suddenly become famous. Many telegraph wires are fastooned from it. The first floor is occupied by scribes and book-keepers in one end, and at the other some ten or twelve skillful workers in iron, who, at forge, and lathe and drill, are solely engaged in making patterns for the genius of the establishment. His iron ideas, in tangled shapes, are scattered and piled everywhere; turninglathes are thickly set on the floor, and the room is filled with the screech of the tortured metal.

Up stairs we climb to a room the size of the building, with twenty windows on sides and ends. It is walled with shelves of bottles, like an apothecary shop—thousands of bottles of all sizes and colors. In the corner is a cabinet organ. On benches and tables are batteries of all descriptions, microscopes, magnifying glasses, crucibles, retorts, an ash covered forge, and all the apparatus of a chemist. At a table sit two earnest men each holding alternately to mouth and ear the mouth-piece of a telephone.

"Well, what are you up to to-day?" asks an acquaintance who has summoned in.

"We have got the Chicago telephone repeater in the circuit at last, and we are now talking through 800 miles of wire, via St. Louis, Cincinnati, Louisville, Washington and Philadelphia—the parabola of the West. It doesn't work well yet. This is the largest circuit ever attempted and it would not be possible without Edison's repeating machine."

In the middle of the room is a man about five feet ten inches high, with a thin face, high cheek bones, and a long lean neck. He would not be picked out in a crowd as a man of more than ordinary intelligence, and he is the person whom a bang-stretcher

étendu, la plume peut être promenée sur le papier avec une certaine vitesse. On n'écrit pas aussi vite qu'avec les plumes ordinaires, mais on écrit à peu près comme un calligraphe qui s'appliquerait beaucoup et voudrait faire de belles grandes lettres moulées.

Le mouvement alternatif est donné à la plume par

zinc. Quand on emploie la plume, on plonge les électrodes dans les liquides; la figure 1 représente la pile dans cette condition. Quand on cesse d'écrire, on relève la pièce centrale, on l'accroche à la partie supérieure de la tige qui lui sert de guide et on préserve ainsi les électrodes du contact des liquides et par suite le zinc de l'usure inutile.

THOMAS A. EDISON, MENLO PARK, N. J., INVENTOR OF THE PHONOGRAPH, CARBON TELEPHONE, DUPLEX TELEGRAPH, ETC.

Thomas A. Edison, the Miracle-Maker of Menlo Park—A Cabinet Minister of Science.

[1878. Portrait.]

The creations of Thomas Alva Edison are the wonder of the world. He has done more than any other man to perfect and develop the electric system of telegraphy, and it still held at work for the second inventions of other improvements.

Edison was born in Milan, Erie county, Ohio, on February 11, 1847, so he is, therefore, only thirty-one years of age. Yet he has already to his credit a list of inventions of his own, and has filed caveats for other inventions of his own, and has filed caveats for other inventions of his own, and has filed caveats for other

EDISON'S MACHINE.

HOW A PIECE OF MECHANICAL INGENUITY REPRODUCES THE HUMAN VOICE.

A GALA DAY AT THE HOME OF THE PHONOGRAPH —IT LAUGHS, IT SINGS, IT RECITES AND DOES EVERYTHING THAT HUMANITY CAN DO —PRACTICAL EXPERIMENTS MADE BY NEWSPAPERS YESTERDAY.

There was a train left this city yesterday afternoon at 3:30 o'clock. It was not exactly a special train, but it had two special cars attached, which were compatibly mendicoupled until their arrival at the Market street depot.

There a delegation of Newark gentlemen awaited it; conspicuous among whom were the following: Hon. George A. Halsey, Senator Kirk, Dr. Green, Postmaster Dobbins of the Board of Education, School Superintendent Barringer, ex-Judge Samuel P. Bigelow, ex-Sheriff Hopper, Hon. George S. Duryee, President of Council Young, Alderman Thirkcuth, Rev. Dr. Wood, Rev. Dr. Howard Smith, Doctors Otis, Osborn, Thomas, Hollon and Wallace, William Clark, Prideaux Jones, Col. Swords, Dr. Thomas Dunn Eng. lish, Daniel Stockton, County Clerk Smith, ex-Register Sharp, ex-Ald. Pennington, John H. Wecker, J. D. Daniels, Andrew Albright, A. H. Lemsley, James R. Pearson, Thomas Smith, T. T. Cairo, Mr. Mellowell, Secretary N. J. Association, Silas Haley, Secretary Boland, H. B. Mandeback, Chas. H. Ingalls.

The Press was represented by Messrs. Woodruff and Hoyt of the Advertiser, Wilson A. Ure or the Morning Call and Dr. Vedder of the Register.

These people had been invited by Mr. Edison to visit Menlo Park, and made a practical test of that most wonderful of all wonderful inventions the phonograph.

Upon the arrival of the train at Menlo Park the gentlemen proceeded to Mr. Edison's manufactory. It was found to be a modest and unpretentious-looking building, only two stories in height, and occupying a position upon a slight elevation westerly from the depot.

Mr. Edison was found in the second story of the building, along side of the electric machine which his genius had seen to investigate. Mr. W. W. Dykington, of the Mutual Insurance Life Insurance Company, acted as a sort of master of ceremonies, although I hailed on signal and took the delighted visit. Mr. Edison's visitors and himself there was the Market street depot, from whence not the slightest formality. As soon as they spoke of the wonders they had seen, the groups were in a genial, off-hand manner made perfectly at home, Mr. Edison with a few remarks introduced his marvelous machine.

He first talked to it himself. He recited: "Mary had a little lamb,

Its fleece was white as snow;
And every place that Mary went,
The lamb was sure to go."

Back from the phonograph came every tone of his voice, every phrase that he made in his reading; it was really a perfect reproduction of Mr. Edison's voice, his sound, and his vocal peculiarities. Next he recited "Jack and Gill," and while he sat with mute lips and folded arms, that remarkable little boy recited "Jack and Gill" as he had done. Then he sang in the instrument; sang "John Brown's body, &c.," and took some every note of that song as clear and as strong as distinct and as accurate as he had uttered it. As soon as Mr. Edison had concluded his little bit of programme, an assistant of his, Mr. Batchelor, who occupied a table quite near to him, sang in another phonograph, the ballad known as "Old Uncle Ned." There was a momentary pause, and then the quaint old song came from the instrument with as perfect harmony as the instrument had received it. Mr. Batchelor performed many other things upon his phonograph, reciting the "Boy's Address upon the Ice" and the Burn Flower," and many others. Upon the invitation Mr. Edison made his machine repeat "Shugen on the Alps," and Mr. Joseph Poole of the Grace Church choir sang a fine Sir old negro melody, Stephen Foster.

The phonograph is in fine style song of the gr. a of Newark's musicales, as represented by Senator Kirk, who, beyond all doubt, has sent to the Paris Exposition the finest piece of workmanship that Newark has hitherto turned out. Then it said a good word for Mr. P. T. Quinn of the New Jersey Horticultural Society, and then it complimented the Reverses. The phonograph has a great many other cute things to the infinite amusement of the audience.

About half-past five o'clock Mr. Dykington called the gathering to order and introduced Colonel Swords, who had been selected as the leader on behalf of the Club to Mr. Edison, which he did with his usual politeness and fluency.

Menlo Park is one among the many garden spots of New Jersey, is one hundred and fifty acres into water, and said to be one of the lordly spots of the country.

We met not old friend M. F. Carman, formerly of this city, who is now located at this place, and has a fine residence near by, and who was kind enough to guide friend Mack and myself to Menlo Park.

Senator John C. McPherson's palatial residence stands in full view, about one mile to the southward.

On a clear day it is said the Brooklyn spires can be plainly seen.

About six o'clock the through mail train on Mr. Edison's visitors and himself there was the Market street depot, from whence not the slightest formality. As soon as they spoke of the wonders they had seen, the groups were in a genial, off-hand manner made perfectly at home, Mr. Edison with a few remarks introduced his marvelous machine.

He first talked to it himself. He recited:

"Mary had a little lamb,
Its fleece was white as snow;
And every place that Mary went,
The lamb was sure to go."

Back from the phonograph came every tone of his voice, every phrase that he made in his reading; it was really a perfect reproduction of Mr. Edison's voice, his sound, and his vocal peculiarities. Next he recited "Jack and Gill," and while he sat with mute lips and folded arms, that remarkable little boy recited "Jack and Gill" as he had done. Then he sang in the instrument; sang "John Brown's body, &c.," and took some every note of that song as clear and as strong as distinct and as accurate as he had uttered it. As soon as Mr. Edison had concluded his little bit of programme, an assistant of his, Mr. Batchelor, who occupied a table quite near to him, sang in another phonograph, the ballad known as "Old Uncle Ned." There was a momentary pause, and then the quaint old song came from the instrument with as perfect harmony as the instrument had received it. Mr. Batchelor performed many other things upon his phonograph, reciting the "Boy's Address upon the Ice" and the Burn Flower," and many others. Upon the invitation Mr. Edison made his machine repeat "Shugen on the Alps," and Mr. Joseph Poole of the Grace Church choir sang a fine Sir old negro melody, Stephen Foster.

The Phonograph and Mr. Edison's Other Inventions.

Everybody is talking about the phonograph —the wonderful little machine that makes it's own music and talks. Even the machine itself has been made to talk, and it is a very interesting thing to hear. The writer went out the other day to Mr. Edison's laboratory at Menlo Park, N. J., and had an opportunity there to see the latest improved forms of the phonograph, together with all the other apparatus with which his inventive genius is constantly experimenting.

Mr. Edison is a pleasant, unassuming gentleman, without the slightest pretension, and dressed like any ordinary mechanic. He is too busy to care about appearances. In fact, they say that when a barber brushes his hair nicely he runs—nicely "runs" it again, as otherwise he can't think. When he is chasing an idea and endeavoring to reduce it to practical form, he stays in his laboratory day and night, has his meals brought to him, and continues in a sort of frenzy of mental concentration until he has conquered his subject. His workshop, or laboratory, is a long, two-story frame building, in the middle of a field, looking solitary, but connected by telegraph with the rest of the world. His operations are so extensive that he has a large staff of assistants to help him experiment and machinists to turn his thoughts into iron. The dozen dwellings which make up the village are all occupied by his employees. Glancing into his laboratory, one would at first sight think it was the machine-shop of a foundry.

The phonograph is a very simple instrument. There is no electricity about it. Its movements are entirely mechanical. Roughly speaking, its necessary parts are four in number: 1. A thin iron plate, such as photographers use for "tintypes," to receive the vibrations of the human voice. 2. A sharp-steel point, or bevel of a needle, attached to the under side of the ferrotype plate, to communicate the vibrations and make marks upon a surface of tin-foil. 3. A sheet of tin-foil so arranged that it will move along under the steel point and receive the impressions, so that the result will be a series of indentations in a row. 4. A mechanical device for the tin-foil to rest on, with grooves for the steel point to press the tin-foil into as it passes along. A machine can be constructed of any shape or size, so long as it has these necessary parts, and less than adjusted together, carefully enough to work with success. The phonograph as Mr. Edison first made it, and as it has been so far introduced to the public, is thus constructed: There is a cylinder about twelve inches long and four inches in diameter, which forms the metal surface for the tin-foil to rest on. This cylinder has a spiral groove running around it, like the groove of a screw, so that the steel point has a long way to travel in following the grooves from one end of the cylinder to the other. The steel point is connected with a diaphragm, a small metal disk, so that it may turn around a center, the point in the center of the groove. Above the diaphragm is located—with the—diaphragm, of course, for the purpose of communicating over it, about it greater force. Now, with wheel and gearing, the cylinder is made to turn in its place, the diaphragm receives the sound vibrations and causes the steel point to move up and down and make such indentations on the tin-foil which in passing around on the surface of the cylinder. The talking may be continued until all the tin-foil has been marked and the entire length of the cylinder has been covered. Then the machine is rewound for talking, all the indentations being used, the steel point back to where it started and the machine over the indentations which it has just made. In this way the indentations make the needle jump up and down, the needle makes the diaphragm vibrate, and thus the exact sounds which were first put into the machine will be reproduced—the rising and falling of the voice, and all combined complaints of a good reciter, laughing, singing, whistling, coughing, the mewing of a cat, barking of a dog, crowing of a crow, etc., etc. The marks on the tin-foil, as they appear to the naked eye, and may be seen anywhere, look like a fine coarse saw. What would not literateurs give for a few words of Shakespeare by Shakespeare himself? What would not scholars give to know the pronunciation of Greek and Latin as it was pronounced by the Greeks and Romans themselves? We have the means now, and in our latest posterity the pronunciation of English as it is correct to-day, and to seal up the tin-foil in one of our greatest museums so that they may be heard thousands of years hence.

Many practical applications of the phonograph have been proposed for present use. A dictionary of words for use from the instrument and used the tin-foil or metal, and his correspondent will place it in a machine at his office and hear the communication. A phonograph with a fat-fish instead of a cylinder is being prepared for such purposes. Celebrated preachers and singers can have their voices preserved, so that persons in towns and cities thousands of miles away can hear them they may happen to be in person. Even the dying words of the faithful can be so hardened that it will repeat the same speech or sing a great many times, and thus Mr. Spurgeon or Miss Kellogg may be reproduced on demand anywhere in this world. Of course, after the tin-foil or the engraving the tin-foil will make ferrotype plates for printing are duplicated, persons will be enabled to buy the speeches or songs of celebrated persons at a steam rate, and will be able to hear them from their own phonographs as they now get photographs into a stereoscope. Letters can be dictated, and dictations may be sold in the same way, the tin-foil going along with the printed text-book. Children can be taught to repeat mental allusions at certain hours of the day. In fact, the applications that suggest themselves are very numerous, and human ingenuity will no doubt devise many that are not yet dreamed of.

The telephone is another invention which Mr. Edison intends to perfect as soon as the phonograph excitement has subsided. The vibrations of a phonograph diaphragm will be magnified and intensified in force by means of magnets and other means, and communicated to a steam whistle, so that the sounds spoken will be converted into a voice loud enough to be heard for miles. Thus a lighthouse can talk with about. "Keep off the coast!" a telegraph operator will shout, "Clear the track!" a locomotive engineer will observe with real voice instead of fog signals, and many other wonderful things will be done.

Mr. Edison has a telephone of his own invention which he claims is many times more delicate than the Bell telephone. He has discovered the property of carbon never before known to science which enables him to produce a telephone much more powerful than any heretofore made. He has recently applied it very successfully with Philadelphia a short time of our visit. He has also a repeating telephone, so that a message can be sent through a dozen circuits, if necessary, it begins to grow faint, reinforce it and send it along with all its force. With a series of repeating machines like this, the telephone may yet be used with success in New Providence as well as from New York to San Francisco.

The duplex and quadruplex telegraph, now used by the Western Union, the Roman-character printing telegraph, the fac-simile pen, and other minor very useful inventions are among the fruits of Mr. Edison's genius; but we leave the phonograph as "king," and all his associates are now directed to its improvement.

THE TELEPHONE TELEGRAPH.

THE PROPOSED EXTENSION OF PRIVATE LINES —DETAILS OF THE SCHEME.

On the door of room No. 44 of the Western Union building on Broadway, are fastened in gilt the words: "Gold and Stock Telegraph Company Superintendent's Office, Telephone-Private Lines." On the glass door of the adjoining room, No. 45 are lettered the words: "American Speaking Telephone." In the adjoining building is the office of the phonograph. In a small room in the rear of President Walker's office, reached by a dozen private through other rooms, are the telephones all in active use. They differ very essentially from each other in appearance, the principle being the same. The instrument in connection with the company's manufactory is a small affair, while that in Mr. Orton's and a fourth private operator was placed in communication with the superintendent, Mr. Charles Cushing, by a wire stretched through an intervening building and in many instances Church, and a fourth private operator was placed in communication with the superintendent, Mr. Charles Cushing, by a wire stretched through an intervening building and in many instances on roofs. Its cover has a melodeon look to it, and is somewhat ornamental. The one private wire connecting the two offices is run through the roofs of the intervening buildings, and is supported by insulators placed on the tops of chimneys. The instruments are in a small box, and are connected by a wire with the battery in the basement. The battery consists of fifty or more cells. It costs one cent.

In what way does Mr. Edison's carbon telephone differ from Bell's?

It will be simpler and cheaper, soon, further and be better adapted to the ordinary uses of the public. What, for instance, can make a telephone with a receiving tube and a mouth-piece as a mere toy, and a thousand miles are the instruments which you propose to introduce commercial use?

Yes, as soon as they are perfected. Our Superintendent, Mr. Cushing, can talk with Mr. Orton in the adjoining office, by which the two can, as Mr. Orton will tell you. They take his invention in his counter form and improve it in many respects. They can now be used for nearly any distance, and have been made almost perfect. They have been at work for a month to repeat messages. As soon as we have the perfect instruments there will be no difficulty in making every office in the city a telephone office, and in every house. We shall lease the original instruments as models and for experiment."

Have you your rights from the Western Union Company?

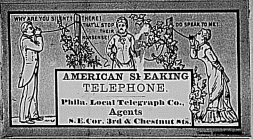
"Only partly. There is a great mistake as to the relations of the two companies. It is not a wheel within a wheel. We are an old company, formed in 1852, and have been doing a large and profitable business of the greater proportion of which is that now the Western Union furnished just—the wires and we the instruments. We have an exclusive business. We conducted the business of our company with that of their own, and contributed largely to the new kind of work—to Gold and Stock reports, to furnish market reports, etc. We have a contract with them for appropriations, but only relations with them are those that are those of a contract by which they furnish us with wires, and we furnish them and allow us the use of those wires at certain long distances at a fixed rate per mile per month. We have no other connection with them. Our capital stock amounting to two thirds of their entire interest. They agree to interfere in no way with our private business and we agree not to interfere with them for public business.

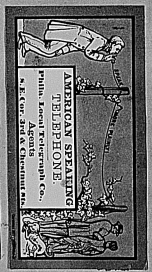
Have you any other business connect with them for the use of Mr. Edison's telephone?

"They have not been served upon at all. They have been offered it, but have declined to accept it in any case as a general rule never connect with the to-be-all their instruments and appliances for our business. The public must be able to obtain a telephone themselves.

"Then you will built our the telephone?"

"Yes. We purchased time's and Hoskins's right-long ago, and are now entitled to the benefit of it. It is our intention to put up telephones in all the cities and to their use by the public. Business only for private purposes and for private lines. For instance, a merchant may have a telephone in his office, and the right to use a telephone in the office of his customer in other cities may also. He wanted to—to—to—





AN IMPROVED TELEPHONE IN YORK.

Buckingham Works, York.

AN IMPROVED TELEPHONE IN YORK.

43

Extracted from the "York Daily Herald" of April 12th, 1878.

Some important improvements upon Professor Bell's Telephone have recently been made and patented by Mr. E. Cox Walker, electrician, (of the firm of Messrs. T. Cooke and Sons) of this city. As it is now pretty generally known Professor Bell's telephone consists of a soft bar magnet, around one end of which is wound a coil of fine silk covered copper wire, and a diaphragm of thin sheet iron or tersnipan. Upon the diaphragm a mouth piece is placed for the purpose of concentrating the voice of the speaker upon the centre of the diaphragm. The coil is connected up to an ordinary telegraph wire, at the other end of which another telephone, various articulate sounds can be conveyed to long distance. Though what at very sound could be transmitted with sound artificial distinctness, it was found both in practice and experiment that the utility of this novel instrument would be much enhanced if the sounds could be by any means intensified so as to relieve the auditor of undue attention, and avoid the necessity for the speaker to speak with more than ordinary loudness. With this view experiments were made with enlarged diaphragms, but these, although giving more volume, became a thickness and comparative intensiveness of the sound. Theoretically, it might be supposed that if the transmitting diaphragm were made to vibrate with a certain force and at a certain rate, that the intensity of the sound developed would be in the same ratio to the multiplication of the receiving and in working out this fact, Mr. Walker has effected a valuable improvement. The improvements consist in it striking or a vibrating the diaphragm and the same time, and directing the impulses so that to each diaphragm there is a corresponding sub-impulse. Instead of using two or four magnets, Mr. Walker adopts one or two magnets somewhat of a horse shoe shape, the coils being connected as for ordinary horse shoe electro magnets, and the connections made with the transmitting wire in the ordinary way. Taking the simplest arrangement as an example, it might be assumed that the magnet is placed in the centre, and in place of being direct to the diaphragm it is divided into four smaller magnets, each of which extends and draws the sound on to the diaphragm covering the magnets. Mr. Walker does not have a separate diaphragm for each pole or coil, but has so constructed the under side of the membrane that it clips to the diaphragm tightly across the middle and around the top thus encircling the coils, and virtually forms them. We had the privilege on Wednesday evening of witnessing some experiments with the improved telephone on Messrs. Cooke's premises in Coney-street, under the superintendence of Mr. Cox Walker. Conversations were carried on and songs were sung with the single telephone, the double telephone, and the duplex and quadruplex system of telephone of Mr. Walker. Comparisons could then be made, and it was found that as nearly as could be ascertained by the sufficient the intensity of the sound transmitted through the duplex telephone was double of that transmitted through the single instrument and the same proportion was found to be maintained in the quadruplex telephone. These results were obtained not only in the transmission of the human voice, but precisely the same effect was observable when the strains of a violin and a small musical box were sent through. The effect, in as of the violin were heard with great distinctness, and the whole of the experiments were of the most satisfactory character. Mr. Walker has succeeded in greatly increasing the intensity of the sound by adding to the number of coils, diaphragms, and corresponding divisions in the mouth piece, and he is hopeful that an octoplex telephone will give right tone the intensity of a single one. The improvements already effected will render the transmission, and especially the receipt of telephonic messages, a matter of much greater comfort and facility. Besides the mouth piece Mr. Walker has patented improved ear pieces, the advantage of which is that the ear pieces being tapered to a small point the sound can be more easily concentrated on the tympanum of the ear without at the same time occasioning any discomfort by the pressure of the instrument, in addition to which two ear pieces can with facility be used at the same time.

THE DAILY GRAPHIC
MONDAY, MAY 6, 1878.

Edison deserves the thanks of the sailor, for counselling Congress to force to some of their own exercises.—Boston Journal.

The Graphic says: "The pneumatic feels its supreme ability. They say does it support—Philadelphia Bulletin.

And then they clinched quite cordial like, Remaining tie for tie;
And when they parted they remarked
In the usual manly way,
—Written paper on the Fat Boston discussion.

[ANOTHER OF '42.
[Cincinnati Saturday Night.]

Edison, inventor of the phonograph, cannot be suffered to have it all his own way very long. Already a steal has appeared in the person of one John Q. Stewart, of Chicago, who, unfortunately for China, who announces a machine called the "Mikrokosm" by which the Atlantic can be crossed in twenty-four hours. The boat is furnished with revolving cylinders in front which throw the water to either side, thus gaining a rapid motion. The machine which is to control by the screw-wheel in the stern as through the air. He claims that his boat, which is to be made of steel, will be light and solid enough that 6 months' life boy would be any one to make. Danforth is confer-ring to organize a company with the necessary capital to control the invention, with Sandy and his money.

EDISON AND HIS FACIES.

Edison, the inventor, has lost an queer ideas about food as about machines. Being tested out to lunch in tish city one day last week, he ordered only pastry, and ate a piece of strawberry shortcake, a piece of mince pie, some cream, and a piece of dumpling, one after the other. He said he had a theory of food: letting that the proper and useful mixture of nutrien was only to be got by the diversity of their diet. "I wish I could subsist on one thing twice a month," he said. "There is then a lightenment and great mental activity as a variety of food. Look at Chiles, fed on okra, and on France, where they cook a thousand times a hundred different ways." Mr. Edison declares that his telegraph, recently purchased by the Western Union Telegraph Company, is "nowise likely to prevent" so many of his employees become they do not use cards. Invented by the way, the "Edison pen" is a most wonderful contrivance and curious properties not hitherto understood, that are about to be of great value to science, especially to chemistry and astronomy."

EDISON'S FRANKENSTEIN.

THE GREAT INVENTOR ESPIES A SPIRIT WHICH HE FEELS IT IMPOSSIBLE TO LAY.

While a Graphic representative was talking with Mr. Thomas A. Edison recently a rather well looking young gentleman entered and was introduced as Mr. Stewart, of Chicago, a friend of the inventor. He was a youth with balding forehead and a pleasant face, and he brushed back with his fingers.

"Well, Mr. Edison, I have been looking for you everywhere," he began, "and I want to tell you not to stay any longer. You are working altogether too much. You are killing yourself. Your health is nearly ruined by your continuous labors. You must not be complete in what you have applied directly to the amelioration of the condition of man kind itself. In human physiology and psychology you are put to with your mental interests. Do not, I know," said he, smiling his head, "this wonderful machine is at your relaxation to play upon as dog [illegible]."

"Well," said Mr. Edison, with a screwed smile, "I do not see what you are doing at. What can I do for you?"

"You are aware, Mr. Edison," recommenced the visitor, "that my interest of our wonderful is that not for sixes. What I want is that you shall [illegible] Science has destroyed the old conception of immortality so dear to our fathers. It shows in the absence of [illegible] and [illegible] Bible, by Glycerine of Darwin, Tyndall and Huxley and their conferers, it is that the material organism composing the human body dissolves at death, and that there is no conscious life after decease. There is an immortality of the material of which the body is composed and the forces by which it moves, but no one forever. We live in our children, in our work and in our influence. But this is sentimental and unsatisfactory to the selfish man."

"Well, well," said Mr. Edison, "what are you driving at, my dear fellow? I do not get the clue."

"Just this," remarked the enthusiastic theorist, putting his fingers in the arm-holes of his vest and pacing against the floor; "I want you to invent an ingredient—an elemental compound—with will give me conscious life in my stead—in other words, give me duration which I can recall next day. Three dreams must be invariably pleasant."

"Are you mad?" said Mr. Edison, leaning forward and putting his hand to his ear, as he is in the habit of doing when persons with whom he is talking do not understand that he is partially deaf.

"Well, Mr. Edison, I have been here and the narrative which go to prove your time and space have nothing to do with sleep—the experiences of Coleridge, De Quincy and Fitz Hugh Ludlow, which show that you may dream a thousand years in half a second."

"Yes," said Mr. Edison, "that is true. I remember once failing from the fifth white asleep, and in the interval between these and the floor the time was so prolonged and my consciousness so vivid, that when I awakened to write it out afterwards I filled fifteen pages of foolscap with the narrative and then did not get half through. Yes, I know that it is a matter of fact that time is not controlled by time or space, but test of that."

"Are you catch my idea?" exclaimed the enthusiast eagerly. "You remember the story of the man who dipped his head in the magic basin of water in Egypt? Between the moment of immersion and the next moment of withdrawal of his head, a century had passed; he dreamed he was married in the interim as a Sultan; was married and had a large family; and was finally the victim of an intrigue; was tried, delivered and beheaded."

"Well, well," said Mr. Edison, somewhat impatiently, "come to the point. What are you going to make of all this?"

"Well, Mr. Edison, we know, do we not, that opium and other narcotics of amazing vividness which are commercially valuable? Hashish or Indian hemp has the same effect. Tobacco users relate a kindred experience. Alcoholic stimulants excite the brain in a different way, but produce the same effect. It is a most important change that no clerk or other employee will need to be trusted with any information as to pending negotiations or orders given. One principal will speak at New York; the other will listen at San Francisco; and each can then look up in his safe a record of what was said.

The best contrast of the future will be drawn by no lawyers, to the inconvenience of the parties, wrangled over by counsel, and from as the blessed hope of a life hereafter, may be the portraits of souls, thousands our sleeping sense, so that when we lie down it will be to an eternity, a pleasant dream. Thus science, which has taken from as the blessed hope of a life hereafter, may restore it. Science answers, "which, if it could be restored—well, there's no one speculating about the results. Death it and that's best. Experience, they what you can do. Young man," and the inventor laid his finger caressingly on the shoulder of the fantastic of ideas, "if your enthusiasm keeps up for ten years or twelve delights during the time in which our minds are governed, it would, perhaps, be well to have some medical friend, with a stomach pump, looking at you every minute. You might overstep yourself, you know."

The young dreamer person out on his hat thoughtfully, and went out without saying a word.

The Public.
NEW YORK, THURSDAY, MAY 2, 1878.

THE PHONOGRAPH.

Forty years ago, when Professor Morse was exhibiting a curious invention in a hall in this city, very few persons realized that a new world, as to all financial and commercial transactions, would be the result. So completely has the telegraph entered into and transformed the processes of business, that men now in the prime of life catch themselves wondering how it was possible to do business at all in the years when they began. A single invention has thus revolutionized the commercial and financial world.

If the anticipations of Mr. Edison, so clearly and modestly stated in his very interesting article in the North American Review, are realized in any considerable degree, another revolution in commerce is at hand. The results of the phonograph, if it accomplishes only what is now expected by shrewd and cool-headed observers, will be incalculable. It must be presumed, also, that this invention like every other which has involved the use of new forces and principles, will prove capable of almost unlimited improvement and application to new purposes. But enough can even now be foreseen to cause the progress of this invention to be watched with the utmost interest. A few of the immediate effects upon business methods may be here suggested.

The time and labor of thousands of clerks can be saved, who are now employed in writing letters from dictation or otherwise. As fast as the principal can utter his directions, the phonograph will yield two copies, one to be filed away by him, another to be sent to his distant correspondent, there to reproduce precisely his own words in his own tones of voice, and also to be filed as the highest possible proof of the transaction. Handwriting and signatures may be counterfeited, and therefore may also be repudiated falsely; it will be more difficult to forge or deny tricks and tones of speech, and peculiarities of grammar or pronunciation. Experts may dispute long about writings; but any jury can judge whether an order was given by a man if, having first heard him repeat the same words on a witness stand, they next hear reproduced, with photographic accuracy, the very tones in which the order was originally given. It will be a most important change that no clerk or other employee will need to be trusted with any information as to pending negotiations or orders given. One principal will speak at New York; the other will listen at San Francisco; and each can then look up in his safe a record of what was said.

The best contrast of the future will be drawn by no lawyers, to the inconvenience of the parties, wrangled over by counsel, and from as the blessed hope of a life hereafter, may be the portraits of souls, thousands our sleeping sense, so that when we lie down it will be to an eternity, a pleasant dream. Thus science, which has taken from as the blessed hope of a life hereafter, may restore it. Science answers, "which, if it could be restored—well, there's no one speculating about the results. Death it and that's best. Experience, they what you can do. Young man," and the inventor laid his finger caressingly on the shoulder of the fantastic of ideas, "if your enthusiasm keeps up for ten years or twelve delights during the time in which our minds are governed, it would, perhaps, be well to have some medical friend, with a stomach pump, looking at you every minute. You might overstep yourself, you know."

The young dreamer person out on his hat thoughtfully, and went out without saying a word.

The check or draft of the future will be a thin metallic strip attached to such paper as is now employed. On the paper will be known stamps and signatures, as now; on the strip of metal will be the voices of drawers and endorsers. To raise a check will be impossible, for no one can interpolate new words in the continuous flow of speech. To forge a check, draft or note, the knave must be able not only to imitate, as now, stamps, forms and signatures, but to mimic known voices with accuracy. Between correspondents, private signs can easily be arranged, which shall amount to all other bearers more carelessness of speech, or peculiarities in the movement of the instrument. It is hard to guess how far this invention may be employed in the prevention of forgery, the authentication of bonds, or the verification of other important papers.

The library of the future will be one which any man can carry under his arm. Bound between proper covers will be a thousand thin metallic leaves *in inches square*, each leaf a volume of 40,000 words. And each book will read itself to a man while he works at his bench, sits at his counter, or eats and smokes; in most trades he will educate himself while he is earning a living. The cost of reproducing a book, if Mr. Edison is right in his belief that phonographic plates can be copied by electrotyping, will be much less than the cost of printing a small handbill. The paper maker and binder and printer will have less to do, but few men will be too poor to own a library. The author can talk to his phonograph instead of laboriously writing; the orator can rehearse his speech, and see how it will sound; the advertiser will send his best recommendation of his wares to as many people as he likes, that they may listen when they have a moment's leisure and the phonograph is not busy.

The business office of the future will be any pleasant room within a telephone district. For Mr. Edison believes that the same instrument can be made both to utter and to record, at either end of a telegraph wire, words spoken at the other end. Jones, then, after he has taken breakfast at home, steps to the machine in his library and hails the main office, "Put me in line with Smith, 49 Broadway." Smith is hailed, and their wires are connected, and they at once do business. Jones offers to buy goods or lands; Smith hears the proposal, and at both ends instruments record it. Smith names price; Jones reponses and wants lower; finally they agree. Ten minutes chat, every word recorded, closes the bargain, and Jones is ready for a trade with somebody else, meanwhile smoking at home. In less time than even rapid transit can take him down town, he can hail and bargain with twenty people, and be able to prove fifty years afterward every word spoken by him or to him. When he needs a clerk or any property he may go abroad unless samples can be sent, but if the inventor does not deceive himself, in the dealings of the future, between business men of the same city or of different cities, transactions by wire will be preferred to personal interviews, because delay in moving about will be avoided, but still more because every word will then be on record.

These things sound like dreams. But the telegraph was a much wilder dream til 1848, and now London orders tea from Hong Kong in "less time no time." Dreams "are such stuff as" we "are made of," and our grandest advances of commerce and industry are but the crystallization of wild dreams into every day facts. It is impossible to guess what transformation in methods of commerce and cost of doing business may be affected within the next decade by the little revolving wheel which a singular man in New Jersey has made to talk.

EDISON'S PHONOGRAPH.

A Pleasant Visit to Menlo Park.

The Talking Machine Tested and Other Remarkable Inventions Examined.

In response to an invitation extended to the Essex Club[sic] their friends by Mr. W. H. Applegate, a party of gentlemen numbering one hundred and thirty-four visited the interesting factory of Prof. Thomas E. Edison, at Menlo Park, on Tuesday afternoon last. The workshop of this celebrated inventor is located a short distance west of the Pennsylvania railroad depot on a plot of land covering about an acre, from which a fine view of the surrounding country may be had. The two-story building, about 25x100 feet, is divided into a machine shop, office and work-room on the first floor, the glass cases in the latter room containing many curious working models of telegraph instruments. Hundreds of electrical batteries of various sizes and forms are ranged on shelves around the room, while the walls and ceilings are covered with a network of wires, a dozen or more, of them leading from the building to different parts of the country. Mr. Edison's electric motor, consisting of a large magnet, three feet long and resembling a tuning fork, which he expects to utilize for running light machinery like sewing machines, was inspected by the visitors as it laid on a table on the upper floor. The electric pen was examined, and a large organ was performed upon by one of the musical experts present. The telephone also afforded considerable amusement to those assembled, who conversed with each other with the greatest facility through ten miles of wire extending in coils from the roof. Dinner was served at the upper floor. The tune, furnished by a tiny music-box at one end of the table, was also heard at the other and distinctly. Many other novelties in telegraphy greeted the eyes and ears of the visitors as they strolled through the rooms; but the chief attraction of Prof. Edison, the Phonograph, was the principal object of interest, and around two of these instruments most of the visitors clustered. Mr. Edison operated one of the instruments, while an assistant, Mr. Batchelor, had charge of the other one. The apparently simple operation of reproducing the sounds of the human voice was witnessed with the greatest delight by all present, and the sheets of tinfoil bearing the dotted lines of sound waves as they appeared from the cylinder were carefully transferred to the pockets as different gentlemen to be preserved as souvenirs of the visit. The instrument consists of a metal cylinder about ten inches long and four inches in diameter, which is made to revolve on an iron bar about three feet long, around the face of the cylinder, parallel to the extension of an inch apart, run delicate grooves. Over these grooves is placed a sheet of tinfoil five inches wide, which is held firmly around the cylinder. The machine is now in readiness to receive sounds, which are transmitted to the tinfoil while the cylinder revolves through a short tube similar to a telephone mouthpiece, and held close to the tinfoil. The impression of sound is given by a metal point attached to the centre of the diaphragm at the bottom of the mouthpiece. The voice of the operator causes the diaphragm to vibrate, and the point thus set in motion makes indentations in the tinfoil over the grooves, each dot representing a sound and conforming their impression to its tone of voice, a loud voice causing a deep impression, and, consequently, more elasticity heard when reproduced. After the operator has recited "Mary had a little lamb," or other nursery rhymes, with his mouth to the phonograph, a small paper tunnel is placed over the mouthpiece, the cylinder is again turned, when out through the funnel come the identical sounds that were uttered by the operator, whistling, singing or ordinary conversation, notes being reproduced with remarkable accuracy. When one sheet of tinfoil had been used as long as the company desired, another sheet was placed on the cylinder for the purpose of recording another series of sounds. It is claimed by Mr. Edison that the sheets taken from the cylinder can afterwards be replaced on the same or a similar cylinder and reproduce the same sounds an indefinite number of times. This experiment, however, was not shown to the visitors, the peculiar cylinder required for this purpose being still in course of construction. Should the effort prove impracticable to confine the original sounds so that they can be reproduced on different phonograph machines, the invention will be valued simply for the novel amusement it affords. Mr. Edison, however, is confident that his discovery will open up a wide field of usefulness for the phonograph. He is an indefatigable worker, and plainly shows the effects of intense mental application, although his youthful, clean-shaven face bows it serious expression when engaged in conversation. Mr. Edison, with his wife and children, lived in Newark for several years before locating at Menlo Park, and evidently finds a large and handsome frame house situated between his shop and the railroad. This corner of Mr. Edison has been an eventful one. Starting poor in life, he became an operator in a telegraph office, and walking from a Western town to Boston, entered an office there in a dilapidated condition and assisted the manager and other operators by his ability to receive a message from the most expert and rapid operator in New York without superior or break, a test that no Boston operator had previously been able to accomplish. Coming to New York, Mr. Edison gave most of his time to the invention of improved telegraph instruments, and has received many thousands of dollars from the Western Union Telegraph Company and other parties for the patents he has secured.

WONDERS OF THE PHONOGRAPH.

Just the Discoverer, Mr. Edison, Says Himself—Even a Constitution.

Telegraphy Revolutionized—The Practical Results.

From an authority so worthy of attention as the inventor himself, we have received explanations to which that new mechanical wonder, the phonograph, can be put. Under the title "The Phonograph and its Future" the North American Review for May-June, which is now before us, contains a paper by Edison, from his experiences when developing his invention, and points out the manner in which the new instrument is to be utilized, and in many instances renders unnecessary, the labors of the telegrapher, the writer, speaker and singer. He undertakes to show that in this new force a complete revolution will be accomplished in the now costly and laborious methods of recording the most important literary records of historical utterances of man can be secured and reproduced at will, and in as many places simultaneously desired. It is with the view of setting intelligent conjectures at rest that the inventor of the phonograph gives his own description of the instrument to the public. He says: "From the very abundance of conjectural and fanciful matter which has been published of late upon the press, the public is liable to become confused and apparently uninformed as to the immediate practical effects of the phonograph than if the inventor himself were confined to certain specific applications and therefore of less interest to the masses." And with regard to the commercial development of the phonograph he adds: "So, the case of an invention of the nature and scope of the phonograph it is practically impossible to foretell it by the, for, to converse a trifle any extent it almost intelligibly."

PRACTICAL RESULTS.

The natural practical results obtained from the phonograph may be set down as follows: The simplicity, permanent retention and reproduction of the most original characteristics of all sounds heretofore designated as "fugitive." The transcription of spoken sounds in numerical form for purposes of communication or as mechanical records.

The indefinite multiplication of any repetition of words, without regard to the existence of the original, and the exactness of the fact that it is a means of communication within itself, and by means of its own mechanism.

Among the more important prospective applications of the phonograph may be mentioned letter-writing and all forms of dictation, books, education, the deaf, the blind, family record and such elementary applications as books, musical boxes, toys, clocks, advertising and signaling apparatus, speaking, &c.

THE LETTER-WRITER PHONOGRAPH.

"The spoken word may be reproduced in mechanical details will be the same as described in connection with the ordinary telephone, and can be recorded either upon a flat plate or disk, with a spiral groove on the face, impressed by the action of the sound; the plate, the grooves are cut varying in depth to suit the pitch and volume of the sound, or upon a cylinder with a helical groove of fall, upon which the record is laid, in the form of a helix, each turn touching the next neighborhood of forty thousand to the inch.

"The practical application of this form of phonograph for communication is very simple. A sheet of foil is placed in the phonograph, the clockwork is set in motion and the mouthpiece held into the mouthpiece without other effect than when speaking to a stenographer, the words rendered and placed in a suitable form of envelope and sent through the ordinary mails to the correspondent for whom intended to the correspondent upon his phonograph, starts his clockwork, and listens to what his correspondent has to say."

HORSE, FOG, SECRETS, &c.

Books may be [illegible] by the electrically-disciplined proficient, and by many [illegible] are especially employed for that purpose, and of course [illegible] each book in the system of electricity, hospitals, the sick chamber, or the [illegible] of the world and announced by the lady or gentleman with eyes and hands busy or otherwise employed; and, in fact, because book when read by an elocutionist is [illegible] read by the average reader. The following record sheet, repeating this book from fifty to five hundred times at will, would cost but a few cents more than would pay the original readers who are [illegible] to read in the phonograph.

"An electrical phonograph may be a private nurse together for children. It is certainly to be invariably excited for the pupil last used, after which he has only to apply to his phonograph for instruction. The child may thus learn to spell, commit to memory, a lesson, &c., &c.

"The phonograph will undoubtedly be literally developed into a toy. Talking and singing phonographic reproduced may marvelous accuracy and power. Thus a friend in a morning call, sing a song which will delight an evening company, &c. As a musical instrument it will be used to enable a master a new air, the child to form its first [illegible] or to help him to sleep.

"A book of 50,000 words upon a single metal [illegible] will require a somewhat strong probability. The advantages of such books over those printed on paper are obvious to most readers. Such books would be confined to where new notes are read." We may add in this connection that phonographic books would become as useful and interesting to the blind as to those who have eyes and to the poor people, the public is liable to become confused and apparently uninformed as to the immediate practical effects of the phonograph than if the inventor himself were confined to certain specific applications and therefore of less interest to the masses." And with regard to the commercial development of the phonograph he adds: "So, the case of an invention of the nature and scope of the phonograph it is practically impossible to foretell it by the, for, to converse a trifle any extent it almost intelligibly."

Commercial Gazette May 5 1878

NEW YORK LETTER.

Edison in a Restaurant—His Theory of Eating—Investment of the Phonograph—The City Telephone System—Newspaper Miscellanies—The Theatres.

Correspondence Cincinnati Commercial.

NEW YORK, May 2.

Edison, the inventor, whose name is now on everybody's mouth, and whose talking phonograph I told your readers something of a few weeks ago, came in from Menlo Park, yesterday, and in accepted my invitation to lunch with me. His eating as we proceeded was so interesting that, absent the subject, as an example.

I had heard his scouting assertion, Professor Edward H. Johnson, tell how difficult it always is to entice Edison to eat when the frenzy of a new invention is on him, and how they have to study his moods and depend the food around on the benches where he will discover it, and I was not unprepared to see nothing bites an epicure.

"I take this eating business" said Edison, as we went up-stairs, "I always avoid it when I can."

"It is a waste of time," I replied; "it seems as if the whole day ought to get swallowed in some mere commercial way." He cut off a suggestion about an eating machine by saying—

"It isn't so much the waste of time, but I don't like food. I have generally been in fine health, but I don't remember when I really liked the taste of food. I never eat for any reason except because Nature obtains a tantrum."

"What'll you have?"

"Anything," said he, "I don't care a rent what it is. Anything but meat, I generally take pastry of some sort at this time of day."

He took the bill-of-fare and told the waiter to bring him some strawberry shortcake, strawberries and cream, and an apple dumpling.

"You won't but beer on such food?" I said, as the waiter moved away, with an astonished expression, to fill our orders.

"No, that's good for me," he replied. "Constitutionally—but he I don't give that identical order! often. You see, Jerome, I have a theory of eating. Now, Yankee—that is the secret of it—eating. The Yankee that eat the most kinds of food are the greatest Nations. They always have been, too, and always will be."

The waiter brought the strawberry shortcake, the strawberries and cream, and the apple dumpling, and arranged them in a semi-circle around his plate, and covered it up so as to hide the tempting question if there was anything more.

"Now, as to what you should eat," Edison proceeded: "The race-cattle Nations never progress; they are the result of self-gratification for the time, they forever. Look at the potato and black-bread eaters of Ireland—the Irish are a race of slaves. The Irish be ireland are enervated by the uniformity of their food. Look at the extravagance who inhabit the Black Forests. On the other hand, what is, that we are in all the highest civilizations, and the most healthy, graceful, enlivened and accomplished. Why, France, of course, where the cuisine is the most varied. When the forests of Europe were all full of wild animals, the people lived principally upon food as nearest to nature as possible.

"How can this application be made?" will perhaps be asked. It is by the application of the ear either the telephone or phonograph.

Both these inventions cause a plate or disk to give out sound, and both depend upon the [illegible] harmony with those of the voice of the speaker. A very simple device may be made by which the ear, vibrating disk may be made to [illegible] the [illegible] of the phonograph, thus enabling the speaker to communicate with his correspondent by the [illegible] of the ear.

The [illegible] of telegraphy can approach that [illegible] combination of the distant end of the wire enables the correspondent, if he is present, to hear it while it is being recorded. Thus we have a mere passage of words for the notice, but a complete and available record of those words as the receiver of the message can economy of time and money so further that [illegible] speaking for whom intended to the correspondent upon his phonograph, starts his clockwork, and listens to what his correspondent has to say."

As machine is now right, and that accuracy in [illegible] is needed to perfect it."

"The phonographs that I have seen, Mr. Edison, have a faraway voice, as if speaking in a distant field or speaking on the other side of the partition; and some of the vowels, as 'a' and 'o,' and several of the consonants, as 'p,' 'b' and 'm' were almost unintelligible. Is this to be remedied?"

"I can do. By merely substituting steel hereafter, I have my self-acting machine as flexible voice is finished. A month ago *it would have no only three months, by carefully I should when first sang from the mouth-piece, by actual measurement, and it simply my words were registered and reproduced from.* I believe the new plate machine will do as well."

DOESN'T WANT TO BE PARSIMED.

The Lotus Club and other Clubs have tried to give Jos a reception, Mr. Edison. The Secretary of the Lotus Literary Association today obtained Cyrus W. Field's promise to preside on a dinner in your honor—"Old Newark?"

Mr. Edison said: "I have heard from several clubs, but I am not anything about this Boys' Club. I don't want to be talked about and bored by people. How are you going to conduct this kind of reception? Are you going on to Menlo Park?"

"Well," said he, with a puzzled expression, "the feeling of his not attractively. "I shall run over a week or two at my old home where people don't cause much, and if they intrude that. I shall take a vacation."

Let me say, here, that Mr. Edison is as unlikely as he looks—girl for the last century. He has made his then his proportion of the brains of the period, and he is a fact, however, for his disinclination to be "interviewed." Besides this, he probably considers that all of his time is now his employer and backers, and as others do who have seen a good deal of it.

THE TELEPHONE AND PHONOGRAPH.

It is not true that he is cloudy and unwell in appearance to-day. He had on a new suit of clothes that was not stained out of consistence by anything unusual. He had on a clean collar and his shaved and changed his shirt every morning ever since he commenced his experiments. He took out new and shiny-toe inventions before he was thirty—one years old. Edison is far above all affectations, either in dirt or dress, and is as simple-minded as a child.

ELOQUENT STONES.

The city telephone system is to undergo a change which is a revolution. Edison's telephone is to be substituted for the Gower-Bell telephone which is a practical contemptuous the City Hall, and diverging to the suburbs. A manager at the center will command and disconnect those wires according to call. For instance, if Mr. Edison wants to have a telephone, calls for No. 171, who has a telephone, the manager takes those two wires together, and the parties enjoy a secret confab without any assistance, and with no danger of being overheard by any third parties. The invention is complete, and on every one who has a telephone will be in the directory of all others who have telephones. The personal conversations will be very great. Those who have acquired no right to a telephone will either have to use a public telephone or trust to the slow messenger, delivery of dispatches at present pre-

of a friend, and, for their entertainment, he sets his phonograph in operation; they listen to the genius of the best operas sung by the most celebrated artists, a grand repertoire such as few concert-rooms could boast of; the most spirit-stirring airs played by full military bands; one of Mark Twain's or Artemus Ward's lectures in the drollest of accents; selections from the Pickwick Papers, Charles O'Malley, Theodore Hook, Washington Irving, Shakespeare and a world of authors. An automaton figure can be introduced, in character and costume, at the will of its owner, and, in obedience to internal machinery, may repeat a speech of Webster or Clay, a philippic by themosthenes or an oration by Cicero.

It would be a difficult task to enumerate the thousandth part of its capabilities. As an aid in the home education of children, an assistant to the parent, it will be invaluable; for lessons, instead of being conned over and learned by rote, will reach the seat of memory by the ear instead of the eye. Again and again, by merely resetting the cylinder, the same lesson will be repeated, whether in geography, grammar, history, arithmetic, it matters not. This marvel of science will rear the utterance of the languages, and French, German, Italian, Spanish, Latin, Greek, Hebrew, Syriac, Arabic will be delivered from the metallic plate on which they have been engraved, with the perfect utterance of skilled professors in these several tongues. It will concentrate in itself the polyglot powers of a Mezzofanti or a Barrett, and will sing or talk with equal facility in every language. Even the accidentals of the standard authors of all countries can be impressed by the steel stylus attached to the diaphragm, and listen to the future declamation. Milton, and Dante, Corneilles and Racine, Goldsmith and Sheridan, Bryant and Longfellow, will give to their rarest intellectual treats; and their works, printed on the metallic page by the voice of a first-class elocutionist, will be delivered in the same resonant tones to the household groups in city mansions or rural homes. The sick-room of the invalid will be cheered by the dulcet tones of music sweetly sounding, and hymns and extracts from the Scriptures will impart consolation in the promise they give of a better life beyond the grave. To them, indeed, the phonograph will be a blessing, if not unspeakable, certainly above all mere pecuniary estimate. Truly Edison, when he discovered the wonder and gave it expression in a form that is in itself a marvel of mechanical simplicity, "builded better than he knew."

But the social revolutions which it will accomplish and the part which it will play in the work of civilization, important as they are, are not more so than the service which the phonograph will render to the varied interests of trade, commerce and the arts, to the merchant, to the dealer, to the manufacturer. Should the head of a firm be obliged to be absent for several days, and compelled in his haste to leave certain matters unfinished, certain orders unfilled, it is only necessary for him to impart the desired instructions to his ~~private secretary~~—the phonograph, and they will be repeated with unerring accuracy, while carrying minute details as to the phonographic sheet, and the judge, in the privacy of his library, will attach it to his cylinder, set the machine by which it is received in motion, and in the library is transformed into the court-room, he is again seated on the bench, and he hears the voice of counsel in behalf of his client. The actor, studying his part, takes from the shelf in which he is to perform, wraps the page around the brass cylinder, winds up the clock-work by which it is operated, and, sitting in his cosy chair, commits to memory the words as they come from the most reliable of prompters—a phonographic sheet.

Through this wonder of wonders the types of children will produce the various sounds of the different objects which they represent, and Noah's Ark and the Tower of Babel in imagnow all the confusion of discordant sounds. Each animal in the toy-shop will be given a tongue, will be heard in his own vernacular, but hear only will the phonograph fail. It cannot reduce to intelligible sounds and translate the sacred voice of the barnyard, the stable, the sheep-pen, the menagerie or the aviary. We can imagine the delight of the mother's or the father's darling as she listens to her waxen-faced doll, with curling tresses and trousseau of the latest fashion, tell the wonderous story of Beauty and the Beast, rehearse the treasures of Aladdin's garden of gems, relate the chivalric deeds of the heroic knight errant, Jack the Giant Killer, or the extraordinary adventures of that enterprising youth, Dick Whittington and his fine conglomerate. What a world of delights it opens up to the young folk, and with what earnest interest they will listen to the soothing, lifeless counterpoint of their little selves, as they hear them talk without tongues, and give forth the lessons they have learned without hearing, and yet retained with a grasp which nore human memory could never equal.

But there is one use to which the phonograph is applicable, and which specially interests and concerns the readers of THE CONTINENT, or at least that large portion of them who take an active part in field sports. The notes of all game-birds can be recorded and produced with perfect accuracy, and thus the most reliable of decoys are obtained; and as with other kinds of game whenever it is desirable to imitate the sounds peculiar to each species. Indeed, through this echo of the roar of the cataract, the melodies of the woods, the music of the mountain streams, the confused sounds of busy insect life, the drowsy hum of summer-heated noon, all will wonderful applications this miracle of science is capable who can predict? It opens up a vast field of which no mind can see the limits; it startles the most credulous with its powers of application. Even its inventor cannot fix the scope or measure of its capabilities. It is indeed the marvel of the age, surpassing even the telegraph, which it will, in all probability, supersede; for the telephone and the phonograph, working in concert, conveying and recording sound, will take the place of the electric current in the transmission of messages, and despatches will be read aloud by the self-same instrument on which they have been written. We are, it would seem, only on the threshold of that boundless domain which holds in reserve still greater wonders than human genius has yet brought to light, or human imagination has ever conceived.

Edison, the inventor of so many wonderful instruments, is a great lion in Washington. He is constantly engaged in giving exhibitions to Congressmen, who find themselves inadequate to express their enthusiasm over the wonders of the phonograph. Among his other late inventions is a new electric car-trumpet. Edison is very deaf, but with this trumpet he can hear a fly buzz a block part of a theater with perfect distinctness

THE EDISON SPEAKING PHONOGRAPH.—This remarkable invention—one of the most wonderful of modern times—is now occupying the electric telegraph—is to be exhibited in Horticultural Hall on Thursday next, and thereafter. We doubt not that such is the great interest in the subject, that it will attract thousands daily to be given here has never failed to welcome what is worthy, and especially when it is based upon such a solid foundation as is this.

1878.

Baltimore, March 19

CRYSTAL PALACE.

A sacred concert, at which Mr. Sims Reeves, Madame Patey, Madame Lemmens-Sherrington, Signor Foli, and Mr. H. Lloyd were to sing, was sufficient attraction to ensure a great number of visitors at the Crystal Palace yesterday. A visit to the Palace was in itself, a reflection of the special arrangements of the management, bound to be enjoyable. The day proved fine, the fields were bright, and green after recent rains, and the trees confidently unfolded their budding leaves to receive the full light of the sun's first real warmth, or greeted gratefully exhibited a wealth of smiling blossoms. Even within the Crystal Palace there is always much of nature to admire. The evergreen ornamental foliage so tastefully disposed among the magnificent products of art could be noticed more freely yesterday than on most other days. In addition the hustle of the busy commerce of the place may temporarily cease. Some of the numerous sights provided for the Easter holidays were to be seen yesterday, although the main feature of the day's programme was of course the sacred concert. For instance, the phonograph was exhibited by the London Stereoscopic Company, who use the English patentees of this remarkable invention. The opportunity of seeing this talking machine was eagerly taken advantage of by a number of the visitors. It was announced in the programme of the day that it would be on view at the Crystal Palace, but that more being found on hand for the proper display of the capacities of a phonograph, of the kind to be shown, the engagement was taken to the Board-room, where, we understand, it will be during the whole of the holidays. The experiments made by the phonograph were very satisfactory. Mr. J. F. Edwards first explained the simple construction of the instrument. Then he said Mr. A. Small, who has improved upon the machine as originally patented by Mr. Edison, of New Jersey, by the addition to it of a clockwork movement which fulfils a very important function, gave exercises of the capacity of the instrument, making it repeat what it had uttered, after even speeches and even their own laughter. The words were spoken into a mouthpiece similar to that of a telephone. The vibrations of the voice affect a thin sensitive iron disc in the centre centre of which is fastened a small hard metal point. The point is adjusted to fit into the narrow groove of a revolving brass cylinder, round which a sheet of tinfoil has been wrapped. It will easily be imagined that as the cylinder revolves the little metal point causes the tinfoil into the grooves and makes the same in a series of marks which vary in their number, in the nullity of their succession, and their depth, according to the vibrations in the sounds emitted by the speaker. The speech being finished, the cylinder is released from the pressure of the little pencil, but the marked tinfoil remains, and the speech can be reproduced by this or any other similar phonograph at pleasure. To reproduce the speech or song as once was necessary to adjust the machinery of listeners yesterday, and accordingly the cylinder was set back till the pencil was opposite the original point of departure. The clockwork which moves the cylinder was set going and the pencil followed the indentations it had previously made. In so doing it re-vibrated the fine discs. These vibrations were communicated to the mouthpiece through a brass mouthpiece in the nature of a speaking trumpet, and the words, and even the voice inflections originally communicated to the instrument, were given back to the audience by this curious mechanism. Coughing and laughing were successfully reproduced. A lady and gentleman by means of a double mouthpiece sang to the instrument a duet. Each was produced by the talking machine, which, however, hardly did full justice to the lady's music. The band of the Scots Guards, under Mr. J. P. Clarke, being in the Palace for the day, Sergeant Hardy played before the phonograph "Ye Land Rose of Summer." To the delight of the audience the phonograph reproduced every note of the air, though not the excellent quality of the music. The phonograph once taken can be used any number of times, and doubtless Sergeant Hardy's solo which is engraven on tinfoil will be reproduced to please future inspectors of the phonograph. One most unfortunate fact, however, is that of musical infelicities, because as the engraving is it can be reproduced backwards or in almost any fantastic order. It is obvious that when experiments are this made with the written music in the tinfoil new combinations of musical notes may be suggested to composers. The music of the phonograph was as yet, however, barely attractive enough to affect the audience in the great orchestra, which had gathered to hear the splendid selection of sacred harmonies there presided by Mr. Manns, the conductor. The Palace band and that of the Scots Guards, uniting with the choral organ, and assistance, as in the Old Hundredth, "And Then the Prince of Wales," and the National Anthem, with the voices of the whole assembled company, produced effects of sound, while also not of the popular vocalists massed at the beginning of this article were exploding as to secure more strictly concerted musical demands for encores. To these demands, however, a good-natured compliance response was made. Mr. Reeves sang an air from the Messiah, and the ladies giving way even to the extent of repeating "Crosbie's Angels" (Shattuck), which was given by Madame Patey, and "Let the Bright Seraphim," which was sung by Madame Lemmens-Sherrington to a trumpet obbligato by Mr. W. Winterbottom. In the evening the band of the 2nd Life Guards played in the great orchestra. A ballad and military concert is promised for Easter Monday.

CRYSTAL PALACE.

Without altogether wanting the attraction which the great glass house at Sydenham was first intended to present on Good Friday, the management has certainly succeeded much to the unconfusion multitudes to which this Jew Jew is regarded simply as a sober sort of holiday. The sacred concert at Sydenham is as good as it has ever been; but it is not relied upon as the sole attraction for this anniversary. Yesterday's programme included, for example, the "Phonograph, or Speaking Machine," at which the scientific world has lately been so much agog. Despite its really marvellous effects, it is one of the simplest pieces of mechanism ever devised. Mr. Edison, the inventor of an electrician—Thomas Alva Edison, of New Jersey—he has nothing to do with electricity in its working and solely mechanical in its construction, down to the smallest detail, may be fairly considered comprehended in a minute's observation. By arrangement with the London Stereoscopic Company, who are the English licensees of the invention, the Crystal Palace directors were yesterday enabled to give a most entertaining series of experiments in their Board-room, the phonograph delightfully and intelligibly explained at each stage. The phonograph in its simplest form is a tinfoil cylinder of a foot round. It and through the middle of this cylinder runs a shaft upon which is cut a screw-thread, corresponding in pitch to the groove. As the shaft works in a screw-box, the cylinder, as it revolves, receives a horizontal or backward screw. Fixed to an adjustable arm placed in front of the cylinder is a disc of thin iron, from the centre of which on the side next the cylinder projects a hard metal point. The disc is clamped at its circumference, but being otherwise left free to vibrate, acts as a system. Each sound-wave therefore the point forward against the cylinder, or rather against a fold of tinfoil, and in its exact circumference, and only forward by a little recess at each end. Into a mouthpiece on the other side of the disc sounds are thrown. They soon to the sounds of the human voice, or, more exactly, to the sounds of the human. An impression is made by the styles on the tinfoil, each vibration causing a short recess. A long sound thus is of indentations in the tinfoil; and when the tinfoil is removed and placed first, the point is set to the end to end with another long line. So little does vary in accordance with the pitch, so little does the length of the notes. The sound is therefore recorded—so to "bottled up" as by vulgar hyperbole, it has been said—in a manner though a short transcript-like, almost over the mouthpiece. This latter sponge can also be reproduced, by means of a launch, to the performance of duets; and in the course of a private hearing, which yesterday intervened, both duets and solos were successfully tried by Madame Lemmens-Sherrington, Mr. Lemmens, Signor Foli, Mr. Manns, and others skilled

musicians, whose acute sense discovered a phonelogism, as yet not described, namely, that the musical sounds are reproduced in a high key, half a tone being the difference. While M. Lemmens and his accomplished wife were singing a duet into the branched mouthpiece something caused them both to laugh, and this instant was faithfully reproduced by the machine. The way for in this the indented tinfoil, being replaced over the cylinder, no matter at what interval of time, enables the rpoduction of the duet. The band of the Scots Fusiliers, consisted by Mr. Clarke, took part with the company's confidence and the great organ, played by Mr. Conrad, and after the concert a selection of named and other pieces was given by the Scots Fusiliers' Band, the conductor being Mr. W. Winterbottom. The great attraction of the concert were Mr. Corder Howes and Madame Lemmens-Sherrington, both of whom received a warm utterte of welcome on the fall of their former triumphs. Mr. Howes sang, first, Cowen's recitative, "Come unto Me," and air, "I heard the voice of Jesus say;" and subsequently, being in fine voice, he rendered Handel's air, "But Thou didst not leave Thy soul in hell," with such magnificent effect that, when called forward to repeat it, the applause with which he was met seemed almost overwhelming. Madame Lemmens-Sherrington sang with the chorus, the "Inflammatus," from Rossini's "Stabat Mater," in which she was encored; "Let the bright seraphim," which she was also induced, though with difficulty, to repeat; and lastly, with Madame Patey, in the duet, "Quis est Homo?" This last association of vocalists gave, with declamatory distinctness, Beethoven's hymn, "Bendelig vanlig," and was loudly called on to repeat it; and she also sang Mendelssohn's "Rest in the Lord." Mr. Edward Lloyd's songs were "Sulpice Arimon" and the air, "Then shall the righteous," from "Elijah;" and Mr. Santley sang "The trumpet shall sound" and Gounod's song with chorus, "Nazareth." In accordance with established and well-approved custom, the visitors joined in "The Old Hundredth Hymn," "Rule Britannia" and "God save the Queen." Three cheers for the Prince of Wales" and "God save the Queen." Then the number of entrances, registered at the turnstiles of the Palace and grounds, was 19,650, many of whom remained to the end.

London Figaro Apr 20 1878

CRYSTAL PALACE.

Good Friday was celebrated at the Crystal Palace with more than ordinary success. Charming weather, an inviting programme, and the well-known standing attractions of the palace combined to ensure a large assemblage of visitors, as wellas to ensure them an unusually pleasant day of enjoyment. Their patronage was pretty equally divided between the fashionable, attractions of the palace itself and the more exciting pleasure ground, which already begin to put on their summer beauties and offer many fair promises to members. Besides the musical and theatrical performances, which constituted the principal feature of the day's proceedings, the programme comprised a variety of other entertainments, some of which are already known more or less to the public—such as "The Cadora Mystery; or, The Sculptor's Model Realised with Life;" the "Living Marionettes and Lilliputian Wonders;" the "Vestibuliad Entertainment and Vocal Illusions of Professor Golding and his Troupe of fairy Folks;" and those which are to be found in the equestrian, the trotting-horse, and the monkey-hosts—there were others with which visitors are not so familiar. There was the Telephone, but even that impressive branch of wonder in scientific discovery was, for the moment at any rate, quite thrown in the shade by the other marvellous favourites called, "The Phonograph; or Talking Machine," which was exhibited at the palace yesterday for the first time by an arrangement with the London Stereoscopic Company, the sole licensees of Edison, the patentee in Mr. Thomas Alva Edison, of New Jersey, U.S.A., chief known hitherto for his improvements in telegraphy and his inventing the carbon pen and quadruple systems of signalling. This latest outcome of his genius—the phonograph—is, in its mere inquiries, an instrument for recording sound, and so recording it that it can be reproduced at any subsequent period. It was exhibited in full operation in the Queen Victoria Jubilee Hall, whence assisted by Mr. J. E. Hough and other gentlemen who have become acquainted with the ways. To be at all appreciated it must be seen and heard again for itself, its mechanical arrangements as have already described in detail. Suffice it to say that the operator has only to shout into something like the mouth of a speaking trumpet, shut up the second with a touch of the hand to a little cabinet labited, keep it hermetically sealed there as long as he likes, and then set the "machine" going to make the sound ascend when it went in. The secret of the thing lies in the sensitiveness with which the sound waves are made to impress themselves—to leave themselves as it were—upon the receiving and preserving medium, which consists of tin foil. Indentations are made on the tinfoil which, when clearly examined, are found to vary in number, shape, and depth to exact accordance with the ventriloquism the pitch, and quality of the sound or voice. These impressions, so to speak, are bottled up, and may be reproduced at any time in the original form, whether it be shouting, talking, singing, or whistling. Illustrations of the versatility of its instrument in that respect were given on the spot. A sergeant of one of the military bands charged the instrument with "Tis true 'tis true, my lord," and it was repeated with wonderful accuracy, though in falsier form. Similar successes were achieved—for instance, in the singing of "Sally in Our Alley," by recitation of the nursery rhyme of "Old Mother Hubbard," and a fit of coughing. No matter what the kind of sound, whether shouting, talking, singing, barking like a dog, coughing, sneezing, or whistling, it is always reproduced, although in a form more faint than the original, and sometimes with an amusing tendency to burlesque, arising probably from defects in the motion or mechanism, which are capable of being remedied in course of time. The pleasure imparted by the exhibition of the instrument and its performances was enhanced by a descriptive lecture, in the course of which Mr. Hough told that as the impressions produced on the sheets of tinfoil were not easily obliterated it became possible to send those sheets of impressed tinfoil to any friends in any part of the world, and afford them the pleasure of hearing our own tones conveyed to them with absolute exactitude. Stereotyped or electrotyped impressions of the tinfoil could be taken, and these so should be able to multiply as well as preserve indefinitely the original speech. There was no end to the uses to which, if thoroughly worked out, the principle might be applied. The instrument might come to take the place of the phonetic system of shorthand, and to be used as a reading aid which it might be charged, to give facilities of famous singers and orators, to play the part of a musical composer, to read in lessons of blind scholars or ignorant persons who had not learnt to read for themselves, and to teach languages. Some of these anticipations may seem rather sanguine, but the fact remains that the phonograph exhibited is a talking machine in a very clever and interesting operation with which to spend a spare hour, and visitors to the palace will do well to make its acquaintance while the opportunity is afforded them. The visitors numbered nearly 24,000.

convenient attachments. Fig. 4 is a front elevation of the electrostatic mastiphier. A is the vulcanite disk on an axis carried by insulating standards. The axis has upon it a pulley which receives a driving cord from a wheel rotated by hand. T, T, are the foil strips fixed upon the face of the disk, and S, S, are studs in metallic connection with the strips T, T. G, and G', are the metallic collecting combs that are attached, and D, D show the position of the conductors at the back. E, E, are the combs for charging the conductors; they also are insulated, and they are connected by the insulated wires, F, F, with the inductors, S, S, are the springs or wire brushes for making contact with the studs. The contact is made when a finger key (not shown) is depressed. The key acts through silken cords which draw the brushes a little way forward: when the key is released they move back out of contact. The magneto-electric machines and the electrostatic mastiphier are employed in combination for the production of the electric light. Mr. Varley causes an electric arc to be formed between carbon points in the magneto-electric machine as is well understood, and in order to render the arc more constant he applies the electrostatic mastiphier, by placing its conductors near the carbon holders, so that a stream of electricity flows to them constantly as long as the light is being maintained. The high tension electricity which in this manner is caused to pass between the carbon points effectually maintains the magneto-electric discharge.—*English Mechanic.*

THE PHONOGRAPH.

Lecture by Professor J. W. S. Arnold.

In response to an invitation from several prominent citizens, Professor J. W. S. Arnold, of the University of the City of New York, lately delivered a lecture at Chickering Hall upon Mr. Edison's recent invention, the talking machine, known as the phonograph. The lecture, says the *N. Y. Tribune*, from which we take our report, was a great part an exposition of the theory of acoustics; the performance of the phonograph was shown to be in strict accordance with that theory. All the experiments shown were quite successful, the Lissajous curves, shown by the electric light, being especially varied and brilliant in their changes of combination. Professor Arnold introduced a singing telephone, which although much commented upon, reproduced, in musical sounds, only a guitar, the notes of songs sung in another room by kid voices. The lecture was an exceedingly interesting one, and showed clearly the relation the vibrations which are caused by the voice in enunciating different syllables; the figures thus obtained flashed each for an instant into view, but they were evidently geometrical forms. The phonograph machine repeated the words spoken to it loudly and clearly, so that it was heard in every part of the hall and gallery. The tone is slightly nasalized and has a strained effect, very much like the voice of a ventriloquist; it is nearly in need of further improvement in quality and distinctness.

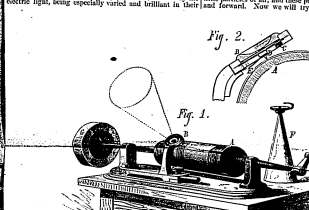
THE LECTURE.

I suppose that most of those who have come on this occasion have gathered together here for the simple purpose of hearing the celebrated machine of Mr. Edison talk. After a while we shall see, I think, that the speaking phonograph, or talking machine, is probably the most interesting piece in acoustics or the greatest mechanical phenomenon of this century. In order, however, to appreciate the mechanism by means of which the human voice is reproduced in such an extraordinary manner, we must first take a rapid glance at the principles and physiology of hearing.

The physics and physiology of hearing—like that of sight —must be studied in two ways: first of all, the actual conditions which are necessary to produce sound, and then the manner in which sound is appreciated by the individual. In other words, we must become fully acquainted with the objective and the subjective phenomena, and then bring these two together. In the first place, both light and sound are phases of motion. Light consists, as we know, of undulations or waves, and sound consists of undulations or waves also; but the undulations or waves of light differ in the manner in which they travel, in which they make their journeyings. The light waves are projected from a luminous body, and take their direction in straight lines from the luminous body, but the direction or motion of the undulations of luminous ether are at right angles to the direction of the [illegible] sound waves are transmitted in a direct line, and we have very much the same phenomena as much as we have in waves of water. That is to say, when a stone is thrown into the water you will notice that from the point of contact in the stone impinging upon the water a series of waves start, spherical in form, and are sent in all directions outward. In order to appreciate the manner in which these waves pass in the atmosphere (because it is necessary we should have some medium by which to propagate or transmit the waves) we will make use in a moment of a little mechanical contrivance, or diagram, which will give us an idea of the propagation of sound. The waves of sound, as they appear in the atmosphere, consist of rarefactions and condensations. Sound can be produced by motion or vibrations in solid bodies as well as in the atmosphere, and we shall see as we study the subject that the ear can appreciate the sensation of sound as readily when it is transmitted through the solid bodies as it can when it is transmitted through the atmosphere. But for the general condition of sound we must have air; we must have some medium by which to transmit the waves from one point to the other, and in general, every body, then, that produces a sound must, more easily, subject the air to vibrations or undulations, and stirs up these waves, and they are carried through the air.

THE MOTION OF SOUND WAVES.

Here we have a diagram to represent what would represent the waves of sound—these light points—and, as I told you, the motion of the particles, which we will study more definitely in a moment, is backward and forward. Now, when a sound is produced, the air is thrown into just the vibrations that we see here. Each one of those waves that we see here is carried on and down in all directions. Now these have actually been seen. A physicist of the name of Seebeck, I believe, has caused a sound from the electrical discharge, to see the waves of sound, and he found that these waves were spherical in form, reflected, and that they followed all of the laws which were found in light. In addition to this he found that these waves were spherical, and that the velocity depended upon the distances each of the waves as spheres overlapping each other, each made up of particles of air, and these particles vibrating backward and forward. Now it will try an experiment. Here we



THE PHONOGRAPH.

have a slit-like formation on the screen, and in this we will be enabled to see the vibrations that are produced, as the particles only for a short distance. The intensity of sound depends upon the distances each of these particles moves. By the generation of the sound it moves from its position, but it is then sent to a certain position and back again in an opposite direction, as you see represented on the screen. So far, then, for the generation of the sound waves. There are a great many other points which we have not time to hurry over to-night in order to get a ground and, consequently, somewhat superficial idea of the whole subject.

Now, the next question is the manner in which these waves can be thrown into action. The sound is produced, as we know, by an electrical discharge in the atmosphere. The electricity being driven through the atmosphere with tremendous velocity, causes the air to be thrown into waves, which cause the sound we recognize as thunder. The electricity we will not discuss. The sound is the chamber. If we agitate any body which is solid, we then produce a corresponding motion in the atmosphere, and these correspond to the vibrations of the body. If we cause a tuning-fork to vibrate, for instance, we produce a musical tone, which is simply due to vibrations of the air in the form of waves. Now, a musical sound, as we understand it, is simply a mechanical disturbance of the air, and, when in vibration, it produces what we call a musical tone.

Now, what the musical tone depends upon certain peculiar conditions, as we shall see, and we shall see also that noises differ from musical tones simply as they can be referred to other peculiarities of vibration. Its sounding a fork we have a pleasant tone to the ear. This is a mechanical vibration of the air by the vibration of the tuning-fork, the effect of which the fork is composed. In a moment we will try another experiment when we throw into vibration a column of air confined in a tube. We can also produce vibrations by a succession of puffs. Here is a little instrument called a "siren." It has a disk which is perforated, as air-chamber. There is now compressed air in the cylinder, and, as it is turned on, the puffs of air escape, causing it to come opposite the opening in this air-chamber very rapidly and evenly, and there is a succession of puffs which can be heard near by, and pretty soon a tone will break forth. [Here the lecturer illustrated his meaning by the apparatus referred to, and was applauded for the success of his experiment.]

SOUND PRODUCED IN TUBES.

The mechanism of the production of sound by this other little instrument is the decomposition of hydrogen by decomposing water with the aid of acid. There is a very fine point, from which the hydrogen burns, introduced into a glass tube. The air passing up through the tube becomes heated and is thrown into vibration by the same air being thrown up and down. If we have a very large tube we shall have a very deep tone, and another is proportional to the size of the tube diminishes. The vibrations are not so rapid in the large as in the smaller tubes, as in the other case the waves being smaller and consequently lighter in tone. The ordinary effect produced in the organ pipes of course we understand. Here we have simply the pulse of air which goes through tubes of various kinds and we get the various tones, as we shall see. [Illustrating the point by sounding certain stops on the organ.] Here we have the air thrown into vibration simply because the bellows, which is on the inside of the organ, drives the air through the speaking into the pipes, and into certain pipes which are known as the diapason pipes, and shocks the air and causes the column to vibrate in the interior of the tube. You see in this tube that I have here, and hold over the flame, the air is thrown into vibrations on account of the heat of the burning hydrogen. [Illustrating it. Applause.] There is another method of producing almost the same general effects which almost every one has heard, and that is the vibration of glass or similar metal which are met with in the little toy called the musical glasses.

Now, then, about the manner of measuring the wavelength of sound. How do we know how long a wave of light is? In measuring it we must have some standard of measurement. First, we must know exactly how rapidly sound travels; second, we must know exactly how rapidly vibrates a tuning-fork which vibrates such as 512 times in one second, and at about the temperature of the atmosphere of this room the sound will travel about 1,142 feet. Now, with this fork we will have wave-length which moves exactly two feet two inches, and the manner in which we have arrived that conclusion is by dividing the rate at which sound travels by the number of vibrations in one second. There are instruments, of course, by which we can measure very accurately the number of vibrations any body produces. Among other instruments we have the *siren*, which I have shown you; and if we produce a tone by this fork, which corresponds exactly in pitch to the tone produced in the siren, we can read off in the index to the siren the number of vibrations produced in a second.

MUSIC COMPARED WITH NOISE.

Now, we come to the question of the difference between noises and musical tones. A noise is the result, of course, of vibrations, but the vibrations are irregular. They do not succeed each other at regular intervals, whereas in every musical tone we have the vibrations following each other at perfectly regular intervals. We say that the ear is pleased with a succession of regular intervals of vibration and displeased with those which are irregular. Noise and a noise then, differ simply in this respect, and, as I have already told you, the pitch or the height of the note depends upon the number of vibrations produced in a given time. If I start the siren once more and allow it to run for a certain length of time, you will notice that as the speed increases the tone becomes higher and higher, until finally we can get quite a shrill tone when what was at first quite a low tone. [The Professor at this point performed the experiment satisfactorily, much applause.] Now, what is the difference between the timbre, or quality, of the note produced by the siren, by the violin, by a cornet, and finally by the human voice? What is the mechanism of production? It can be answered in a few words. Every time a musical sound is produced, such as we have already have in the plucking of a string or by the sounding of a fork, we hear not only one sound, but a great many sounds, and the other sounds are known as over-tones or harmonics. The fundamental tone, which is the principal one, and which we can distinguish by sounding the tuning-fork carefully. Now, yes, if I can produce another tone to the tuning-fork. [Doing so.] There is a different one, and [illustrating with another tone] is still a different tone. But by sounding them together when the fundamental tone is produced, but there is a certain quality we find as we hear them especially. Over-tones, then, give the peculiar quality to the various kinds of instruments and to the human voice, and we find now over-tones are produced in the same mathematical ratio. For example, if we have a note "C" as the starting point, we have the next octave to its octave, which has twice as many vibrations as the original note. Then the next over-tone or harmonic is the fifth above this octave. Then we have "C," and then "E flat," and so on. We have a succession of tones which are related with the fundamental tone, and these tones have the ratio of vibration of 1, 2, 3, 4, 5, 6, 7, 8, 9, 10. That is to say the first over-tone or octave of the fundamental tone has two times as many vibrations a second, the second three times as many, the third four times as many, and so on. Now, it depends upon the number of over-tones and their ratio as they mix with the fundamental tone whether there is produced either the sound of the violin, the cornet, the trumpet, or of the flute. If we take, for example, on the organ a bourdon or a clarinet stop, we have a hollow tone. Now we will take the trumpet stop, and have a piccolo. See how different they are. The human voice has its peculiarities in the same way, and if we take the human sound must be analyzed very carefully, so that the number of over-tones and the peculiar pitch of these will be ascertained, and in this manner we can appreciate the various qualities of sound in the timbre.

THE MECHANISM OF HEARING.

Now let us consider some of the points in connection with the perception of sound by the ear. The ear is a very curious piece of apparatus—the most complicated probably of any piece in the body. The ear is capable of appreciating about eleven octaves of sound. The eye is capable of appreciating but one octave in color, so that the ear has a far greater power of appreciation than the eye. There are certain peculiarities in connection with the ear by which we are enabled to appreciate these sounds, and we must not forget that our appreciation of sound—the subjective phenomena of sound—is, as we already say, very different from the actual condition of things or of matter which produces the sound. Sound consists of vibrations, and the ear takes these vibra-

tions by a peculiar sympathetic process, which we will understand later on, and the brain then has generated in it a peculiar condition which we understand as sound. If we excite the nerves which go to the ear we feel no pain, but have a rumbling sound. If the irritation be even, so that the vibrations or taps of the nerve follow each other at regular durations and equal intervals, music is the result; if irregular, noise is the result; but the acoustic nerve can transmit no other sensation to the brain but that of sound. In like manner the optic nerve can transmit no other sensation but that of sight. If it be wounded, a flash of light follows; if the acoustic nerve be touched, a sound follows. And you know there are some nerve diseases, the result of disturbances occurring in the ear, where there is a continuous sound or humming kept up, and this gives us an idea of the peculiarities of these nerves. We can appreciate, then, the subjective conditions, and we will study now the manner in which the sound is carried to the ear. There are two distinct sets of apparatus in the ear, one for the reception of the sound and transmission of it externally, and then the internal arrangement by means of which the sound is received and transmitted to the brain.

CONSTRUCTION OF THE EAR.

We have on the external portion of the head what is called, ordinarily, the ear. Now, this is supposed, in a human being, to be of little account so far as collecting sound is concerned, because from records we have of practices in savage countries, where the ear has been cut off, we have found that the hearing is scarcely impaired; but in the lower animals, undoubtedly, by putting the ear in various positions, they can collect the sound, and cause it to enter the interior portion of the ear. In the interior of the ear, as we pass in from this exterior portion, there is a little piece of membrane stretched across, which can be described as membranous tympani, and its means of sound impinging against this cause it to vibrate, and the vibrations are transmitted, and set in vibration, by means of a peculiar chain of little bones, another membrane, and this enters a cavity filled with fluid, and within this cavity are the filaments of the acoustic nerves. These filaments are so fine as to little strings, act by sympathetic vibrations when placed in the tones—not only the fundamental tones, but all the overtones which are necessary to exist in every musical sound—and there vibrate according to the intensity of the original tone produced.

This particular part of the mechanism of the ear is inclosed in a bony box, and the complicated arrangement which is here met with is enough for a life-long study. The general conditions which I have mentioned are the most important of these carefully protected, that we have waves produced in a fluid, and that the undulations or waves in this fluid are the direct means by which the terminations of the acoustic nerves are set in motion, and these produce a sensation of sound. Now, a question would naturally arise as to whether or not these little membranes do not possess a fundamentalness. If this membrane were simply free, if it was simply stretched around an opening with nothing else in connection with it, we would hear constantly, when a fundamental tone was sounded, this ringing in our ears; but nature has provided a peculiar arrangement which we find holds good in physics, and which you will see to be beautifully represented in the talking-machine here, namely, that it has damped, that it has a certain fundamentalness. About the center there is a little bone which is attached to this membrane, and this is in connection with several other bones, which I will not now indulge. Now, if we apply this to the central portion of the membrane, it will not then respond to the fundamental tone, but by forced vibrations other tones will be transmitted, and we will not have a confusion of the fundamental tone continually thundered in our ears. And this membrane, instead of being flat, is stretched backward, and this kills, more than anything else, the fundamental tone. The result is that we have a perfect arrangement for transmitting sound.

VIBRATION OF WAVES CAUSES ON ITS SOURCE.

Here is a little piece of India-rubber with a little mirror in the center, and when certain tones are spoken in this tube which is the carrying portion of the ear, we shall see that this is thrown into vibration. I will generate here an intermittent of light from the electric lamp. Now you see the light upon the screen, and if we sing a note in the tube, you will see the membrane is thrown into vibration. If those vibrations could be photographed we could analyze the musical tone character of the harmonics. Now we will say the word "ah," and you see the bulging the notion to the word" and now when I sound the vowel "a" we see also the peculiar effect produced in the membrane. [Applause.] Now there is one method of analysis of tone.

Now then let us follow out completely the mechanism of the production of the sensation of sound. The wave is generated, and it throws into agitation the membrane, tympani, and this membrane carries it into the interior of the ear by means of a chain of bones. One of these bones comes in contact with another membrane situated deeper in, which closes over a cavity containing fluid. This fluid receives the wave impression, and as this is received the undulations are transmitted deeper into the recesses of the ear, and the arrangement here which receives the waves or vibrations and throws into agitation the fluid is called the cochlea. This contains about 3,000 in the ear, and these little cells which are in union or sympathy to the peculiar tone that has been produced by the sound. As they vibrate they agitate the internal filaments of the acoustic nerve, and this the sound is transmitted to the brain. This entire part of the ear is very complicated in structure, but we shall be enabled in a measure to see the principal part where the sound is supposed to be received. [Illustrating on the screen.] There is the bony structure of the ear, seen from its exterior entrance. Here is the membrane attached to a bony structure which is receiving the vibrations, and here is one attached to the hammer.

We can hear a tone which corresponds to about sixteen vibrations in a second; we can hear a tone which consists of about 40,000 vibrations, but when we get below about forty vibrations there is produced what would be called an unpleasant sensation, which is more than a musical tone. On the other hand, when we get above 4,000 vibrations there is a shrill scream. Music then consists of from 40 to 4,000, but the complete compass of the ear is from about 16 to 40,000. These little strings arranged in the ear are capable then of giving us this long variation, and not only this, but our appreciation of the part of an interval between two[illegible]

[illegible]ake for example what is called a full tone or a whole. [illegible]touching a key on the organ. Now the next interval, a whole tone is this [striking it], and a half tone is very close to it. The ear, however, can detect the difference between the 9/8 part of one of these tones and 17/16 part. In the ear there are

Fig. 3.

THE LISSAJOUS CURVES.

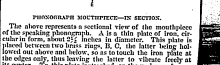
I will show you the experiments of Lissajous, where we have tuning-forks that produce different musical intervals, and they are each caused to vibrate so as to produce reflected rays of light from a mirror attached to each which these fall into which can be worked out by mathematics, so that we can understand the relation of the mathematical ratios of the vibrations caused by Lissajous' forks are simply conditions of the pendulum vibrations. It will simply show you the manner in which the vibrations appear when one fork is vibrating horizontally and the other [illegible]. I will throw a beam of light from the sun, so that it strikes a mirror. The beam of light is reflected to the screen, and you see that the fork is vibrating horizontally. Now, when both of these forks are kept in perfectly even vibrations by means of electro-magnets. The fork is slightly out of tune so that we can see the manner in which these waves are following each other, and when the proper intervals are not exactly tuned, and you will see a perfect figure which represents the interval, and there will be a perfect figure of the octave in this figure known as the waves. When their crests agree with each other in a similar way, but there is somewhat complication, that is, one fourth above the fundamental note. The nearer we approach the octave the more simple is the figure. These are the intervals which can be shown, but that is not necessary.

SCIENCE.

Voice is produced by vibrations of what are known as the vocal cords. The vocal cords are little membranes situated in the throat, and by the action of certain muscles, can be made tense and lax, and in the air which is driven out by a respiratory effort the cords are caused to vibrate, and they are thus transmitted to the column of air. Now we have the cavity of the mouth, which contains the teeth roof of the mouth, and when we enunciate certain words we approximate the tongue, teeth, and lips, and these are what are called the labials. We can thus bring back the soft palate, and the tongue, and the tongue for producing what are called the gutturals. Touching a key on the organ[illegible] consists of a funnel-shaped cavity which is capable of being changed by throwing into agitation the vocal cords, which are set in vibration by the expiratory air we send upon it by embouchure, the vocal cords being simply a tongue of metal over which is sent in order [illegible] pressure. Now, in order to appreciate these sounds, we can have in the mechanism of the voice the vocal cords, and the resonance and the guttural tones, and all of these which are common pure musical tones which are generated in ordinary conversation. By combining the two we have spoken language. If we cause the voice to throw a membrane into agitation which has any electrical connection with agitation, we will then produce vibrations which will represent the vibrations. Now I have a contact-arrangement and a singing telephone upon the table, and I shall ask my assistant, Dr. Bruce, to tell me when he is ready, and when he sings in the mouthpiece of the telephone it will be heard, but not be with the quality, which is represented in the latter body. In the place where the singers are fastened on the end of a piece of wood glued firmly to the top of the diaphragm. Secure upon that has soft iron plate, and the ends of this magnet are brought opposite this iron plate. Now, at the other end where Dr. Miller is, there is a membrane made of paper, and in the center is a little piece of metal, which is in the center of the circuit, and the pin which makes or breaks the circuit as the vibrations of his voice are brought against the membrane. [The tuneswung by Dr. Miller were distinctly heard, but with the quality of guitar music.]

By a combination of pipes in this organ [the large organ in the hall] there is what is called the *vox humana*, which gives a very curious effect [illustrating it on the organ]. It is simply the reed pipe, as it is called, which is shortened, according to the description given to me by one of the gentlemen who manufactured the organ. It is found up or confined and carried off to a great distance from the organ, and opens, in this case, in the vestibule.

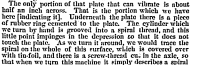
Now, if you are perfectly quiet, we will see if it is possible to have this speaking machine of Mr. Edison's recite to you something about Mary and a little lamb. [Laughter.] Now this is nothing but a mechanical contrivance. Professor A. M. Mayer has recently written an elaborate description of it, and he speaks of a celebrated speaking machine constructed by Professor Faber, of Vienna. The consisted of a machine that represented all the parts of the head and pantuts. There was a reed to take the part of the vocal cords, an oral cavity which have its shape changed by depressing keys on a key-board, a rubber tongue and lips to make the consonants, and, a little whistle to imitate the threat to make the Hz. This was simply the result of experimentation in order to produce each of the different articulations in order to produce each of the different sounds. Without question it would have to be produced, but it is found to be easier to imitate [illegible] by machinery, however, which has been accomplished. Here is simply a piece of brass plate, about 6 inches long and 1½ inch in diameter, and it is clamped at each end between two rings. These pieces of India-rubber are pressed in between these two rings so that the ferrotype cannot sound its fundamental tone. Put will only respond to what are called forced vibrations. Now, upon the under surface of this plate there is a little steel point, which is attached to the plate by means of a rubber ring intervening between the plate and the steel point. [Here the Professor drew a section of it on the blackboard.]



PHONOGRAPH MOUTHPIECE—IN SECTION.

The above represents a sectional view of the mouthpiece of the speaking phonograph. A is a thin plate of iron, circular in form, about 2½ inches in diameter. This plate is placed between two brass rings, B, C, the latter being bolted out above and below, so as to inclose the iron plate at the edges only, thus leaving the latter to vibrate freely at its center. To this plate fastened, on the under surface, a small piece of steel, D, and a fine steel point, E, is affixed to the rubber. It will be seen that the point, E, is so adjusted that when the plate A is thrown into vibration by the voice, C, the vibrations of sound produced in speaking will be communicated to the iron plate, A, thus causing the steel point to be depressed and raised, these motions succeeding each other with a rapidity depending upon the rate of vibrations in a given tone of the voice.

The only portion of that plate that can vibrate is about half an inch across. That is the portion which we have here [indicating it]. Underneath this is placed a piece of rubber ring cemented to the plate. The cylinder which we turn by hand is grooved into a spiral thread, and this little point impinges in the depression so that it does not touch the bottom. The point is so adjusted that it makes a mere impression on the surface of this cylinder, which is covered over with tin-foil, and there is a screw-thread on, in the axis, so that when we turn this machine it simply describes a spiral on the surface of the cylinder. All that it is necessary to do to make the machine talk is to put on a piece of tin-foil.



SPEECH TRANSCRIBED ON TIN-FOIL.

The needle simply is to make a very light groove, and then you talk against this diaphragm, and by a paper cone of this construction [exhibiting it]. Now you will hear me reverse the motion and turn the cylinder backward the way it was at first, and we have repeated what was said. [confusion is not very great yet, as the cylinder is not perfected. When the plate is thrown into vibration the point, pushes down and makes indentations in this tin-foil. These indentations correspond to the peculiar form of wave-motion which have been uttered by the mouth. The consonants in this machine are not very distinct, but the vowels as you see,

...ps a little bone which is stretched as full a membrane, and this is in connection with several others and acts as a damper or ...ke. Now, if we apply this to the central portions of the membranes, it will not respond to the fundamental tone; but by forced vibrations from the other membranes, as before, we will not have a confusion of the fundamental tone distinctly drummed in our ears. And this membrane, instead of being flat, is stretched backward, and this kills, more than anything else, the fundamental tone. The result is that we have a perfect arrangement for transmitting sound.

VIBRATIONS OF SPECIES SHOWN ON THE SCREEN.

Here is a thin piece of vulcanite which is fastened in the center, and when certain tones are spoken in this tube, which is the carrying medium, the whole of the vulcanite is thrown into vibration. I will generate here an intense sound of vowel vibration, and you will see on the screen the light spots widen and widen, and I could go on doing this till by the membrane is thrown into vibration. If the vowel tone could be photographed we should analyze the sound and character of the harmonics. Now we will say the words "one," "two," "three," following the action to the words; and now when we sound the vowel "o" we see also the peculiar effect produced on the screen. [Applause.] Now I will sound a series of tones.

Now then let us follow concretely the mechanism of the production of the sensation of sound. The word is generated, and it throws into agitation the membranes tympani, and that membrane carries it into the interior of the ear by means of a chain of bones. One of these bones comes in contact with another membrane situated deeper in, which closes over a cavity containing fluid. This fluid receives the wave impression, and as these are received the undulations are transmitted deeper into the structure of the ear, and the structures here take up the waves or vibrations and throw into agitation certain little fibers, of which there are about 3,000 in the ear, and these little spots vibrate in unison or sympathy with the peculiar tone that has been produced by the sound. As they vibrate they agitate the internal filaments of the acoustic nerve, and this wave of sound is transmitted to the brain. This curious part of the ear is very ex- quisitely constructed in structure, but we shall be enabled in a moment to see the principal part where the sound is supposed to be received. [Illustrating on the screen.] There is the drum cavity of the ear, seen from its exterior surface. It is a little membrane attached to a bony structure, and projecting out toward the center, where it is attached to the hammer bone. We can hear a tone which consists of sixteen vibrations in a second. Now when we put below about forty vibrations there is practically what would be called an unpleasant sensation, which is not to be considered a musical tone. On the other hand, when we get above 24,000 vibrations there is a shrill scream. Music then consists of from 40 to 4,000, but the complete compass of the ear is from about 16 to 40,000. These little strings arranged in the ear are capable then of giving us this large variation, and not only this, but an appreciation of the [illegible] of an interval between [illegible] Take for example what is called the full tone or a whole [illegible] [touching a key on the organ]. Now the next interval—a whole tone is this [striking] [illegible] and a half tone is very different, you see. The ear, however, can detect the difference between the [illegible] part of one of these whole tones or [illegible] part of a half tone. In the ear these fibers are

THE LISSAJOUS CURVES.

I will show you the experiments of Lissajous, where we have tuning-forks tuned to each other at different intervals, and they are each caused to vibrate so as to produce reflected images on screens. There are certain laws which these follow which must be worked out by mathematics, so that we can understand the relation of vibrations to each other. The Lissajous curves, or Lissajous' forks are simply conditions of vibrations in harmony. It will simply show you the manner in which they are produced. Here are two forks, the tines of one being placed to the other. I will throw a beam of light from the lantern so that it strikes a mirror. The tines could analyze the sound of the first fork, which is vertical, to the second, which is horizontal. The forks are here in perfectly even vibrations by means of electro-magnetics. The forks are slightly out of tune so that they will come to unison when the intervals are not exactly tuned, and you will see the figure which represents the interval, and there will be backward and forward phases in this figure known as the waves. When the forks are tuned with each other we have a perfect figure. When there is any difference the figure changes backward and forward in its recursive and positive phase, as it is termed. How [referring to the screen] we have a circle which is the perfect figure. Now you see that circle turned so as to form an ellipse. So the lines cross and go back again to a circle. It will take a moment or two to put in another fork, and the next one will be an octave with just double the number of vibrations. The forks are also slightly out of tune so as to show all the phases of their figure. Now the figure produced by an octave will be resolved into a circle. Here we have an octave which is resolved into a circle. Now we will try another combination, where the figure will be changed. We will take one that is somewhat complicated—that is, one fourth above the fundamental note. The sounds of the notes are the more complicated in the figure. There are other intervals which can be shown, but that is not necessary.

RELATION OF VOICE TO SPEECH.

Voice is produced by vibrations of what are known as the vocal cords. The vocal cords are little membranes situated in the throat, which, by the action of certain muscles, can become tense and lax, and the air which is driven out by a respiratory effort throws these little cords into vibrations, and they transmit the vibrations to the column of air. Now we have the cavity of the mouth, which contains the teeth [illegible] of tongue, the hard palate and the soft palate, and the [illegible] and when we enunciate certain words we produce these [illegible] and the consonants. We make use of the lips in pronouncing [illegible] the consonants. We make use certain powers back in the throat, called the labials. We use the tongue for producing what is called the gutturals, and the tongue for producing what is called the glossal sounds. All of these [illegible] are the result of changing forms of the mouth cavity. The vibrations are set up by throwing into agitation the vocal cords, which are struck on the same principle as the reed pipe in the melodeon, the reed pipe being simply a tongue of metal over

PHONOGRAPH MOUTHPIECE—IN SECTION.

The above represents a sectional view of the mouthpiece of the speaking phonograph. A is a thin plate of iron, circular in form, about 2½ inches in diameter. This plate is placed between two brass rings, B, C, the latter being hollowed out above and below, so as to touch the iron plate at the edges only, thus leaving the latter to vibrate freely at its center. To this plate is attached, on the under surface, a small piece, D, of hard rubber, with a point, E, is affixed to the rubber. It will be readily understood from the above that when the lips are placed at the opening, B, of the ring, C, the vibrations of sound produced in speaking will be communicated to the iron plate, A, thus causing the steel point to be depressed and raised, these motions corresponding each other with a rapidity depending upon the rate of vibrations in a given tone of the voice.

The only portion of that plate that can vibrate is about the size of the inner circle. That is the portion which we have been indicating it). Underneath the plate there is a piece of rubber tubing, which is not shown. The cylinder which we turn by hand is grooved [illegible] spiral thread, and this little point impinges in the depressions, but it does not touch the plate. As we turn it around, we would trace the spiral on the whole of this surface, which is covered over with tin-foil, and there is a screw-thread on, in the axle, so that when we turn this machine it simply describes a spiral on the surface of the cylinder. All that it is necessary to do to make the machine talk is to put on a piece of tin-foil.

SPEECH TRANSCRIBED ON TIN-FOIL.

The needle simply is to make a very light groove, and then you talk across this plate or through a paper cone of this construction [exhibiting it]. Now we have simply to return the needle and turn the crank again in the same way as it was at first, and we have repeated what was said. The loudness is not very great yet, as the invention is not yet perfected. When the plate is thrown into vibration the points go down and makes indentations in this tin-foil. Now [illegible] corresponds to the peculiar form of vibration [illegible] uttered by the mouth. The consequence is that [illegible] as you see.

A VISIT TO EDISON.

CATH TALKS WITH A PHONOGRAPH.

The Inventor in His Workshop in New Jersey—Some of His Remarkable Discoveries—The Phonograph and the Kinetoscope, and their Possibilities in the Future.

Special Correspondence of THE TIMES.

MENLO PARK, N.J., April 21, 1891.

This morning, with General Cowen, the keen editor of Allentown ("Hold the fort, I am coming!"); General Stewart, the fashionable correspondent of Savannah, and Mr. A. W. Dimmock, of the New York Stock Exchange, I visited Edison, the inventor.

We left Elizabeth in Mr. Dimmock's carriage at half-past ten, whence it is about twelve miles to Menlo Park by the Pittsburgh stage road. A morning filled with Sunday wine and stirring almost sacramental sympathies executed as with twittering sparrows, green leaf twigs and tickling waters, across the Rahway river and up the south branch to the plateau above the Raritan River Valley. There the Blue Mountain line runs directly to the near West, and the scattered homes of Menlo Park lay away the rolling green hills. This was meant to be a Sabbath-hallowed day in the spectacular days, and now consists of thirty or forty frame villas, in long lots, for three or four miles from Perth Amboy, which is at the mouth of Raritan, and in Middlesex county, New Jersey, on the line of the Pennsylvania Railroad, twenty-four miles from New York and seven from New Brunswick.

SMOKY SURROUNDINGS.

Besides the railroad track is a light-colored frame house with darkened shutters, with a wide shallow and with cane-guides in the roof. It has no shade around it, but is closed solidly in the back corner of the up-lifted lot. There is no sign of professional life and only a child is seen surveying us from the back door. In front and not may be seen a few thousand dollars. Crossing the railroad, we turn to the left on a

He Is a Great Man Now.

Mr. Edison, as a young telegraph operator at Memphis, was known for his quaint sayings with which, in odd leisure moments, he illustrated the Southern passion for epigram. A saint was to convert the halls of his gi's and j's into faces, with the usual lugubrious expression imaginable. Another habit was to draw a railroad curve around the room, with a train of cars at full speed. At the first car was a T, on the second T. Then a figure 2, then the figure 3, and so on to the next, was spelled out, and the last car, being impossible to number, was "30," or "No more." On some occasions, some time, until a Memphis editor published a paragraph about the highest name he could think of, the latter proceeding to them on the ground that the thing was a hoax, up one night and in alarming numbers in trying to find appropriate cuss to represent the feelings. The man of the "illustrated name" in question was exceedingly sensitive.—*Buffalo Express.*

DAILY DERRICK.

TUESDAY MORNING, MAY 7, 1878.

STRAY SAND.

"In the bright lexicon of youth," mused grandfather Lickskillet, yesterday evening, "there is no such word as fail, but holy Moses! how the middle aged people are just more than rushing in their voluntary petitions 'before the Ax! Ax is repealed!"

EDISON'S LATEST INVENTION.

Yesterday a stranger man, carrying what appeared to be a small coffin, paused in front of the Oil Exchange. He was a sad-faced man and his black suit glistened in the sunlight like a coat of armor. He put down his strange burden, and leaned to the man standing around. Then casting his eyes up at the building, he began:

"Gentlemen, I congratulate you. You have reared here a structure which is second to none in the country. When you shall have taken to that bosom from whence no traveler returns," and he glanced sorrowfully at the little coffin, "this beautiful building will remain a monument to your energy and enterprise.

"But, gentlemen, pose as I may serm, great as the contest is between us, I have that in this little box before me," and he tapped the coffin reverently with his cane, "which I would not exchange for all the wealth of your Oil K ginos. It is, gentlemen, and he began to unscrew the lid, while the crowd involuntarily shrank back; "it is, gentlemen, a rat-trap which I am introducing for Mr. Edison, of Menlo Park."

The crowd closed up again.

"It is his latest invention and, as he says himself, his best. I have handled a great many rat traps in my life, and I can safely say that this one knocks the socks off of all of them. Don't crowd, too close till I show it to you," and he took off the top and exposed a box with a lot of spasmodic communicating with each other by little doors, windows and openings of one kind and another. "The great inventor named this the 'Cliche Rat-trap,' because it operates off the same principle as a savings bank.

"You see the rat reads the cheese and enters by the front door," that the trapman indicated the mystified with his cane; "thence in quest of the cheese, which is a sort of *ignis fatuus*, though that's none, which admits him to parlor A, or the Cashier's room. This door closes behind him, and he passes thence to parlor B, or the Directors' room; this door closes behind him, as before, and he proceeds to parlor C, as the President's private apartment. By an invention arrangement the closing of each little door removes the chairs into the next room, in this way always keeping it one room in advance of the rat that seeks it —until the last room is reached, (parlor D,) when it is seeing instinctively to the front apartment for the allotment of another victim. Once inside of a door, no rat can get out, but rats on the outside can get in, and do get in, until the trap is full."

"What's all that got to do with a savings bank?" asked a receiving teller who was in the crowd.

"Everything, my dear friend, everything," replied the strange man; "because, you see, when the trap is full it closes—likilities large; so nie nothing."

"THE TELEPHONE."

FRIDAY.....May10

1878

What is the Telephone?

We were surprised to hear this question frequently asked since our last issue, as we supposed every one was acquainted with the construction and uses of this wonderful yet simple invention. So wonderful, that the examiner a week in its presence, with no thought—Is there any limit to man's inventive powers? So simple, that a person will involuntary exclaim, Why didn't some one think of that before? Therefore in order to inform some, who as yet are not acquainted with this great *little* machine and to show the appropriateness of the "TELEPHONE" as the title of our paper, we will give a short sketch of the inventor and this, his most wonderful and useful invention.

Thomas A. Edison is rather under medium size, about five feet seven or eight inches in height. His face is smoothly shaven and his hair is soft, black and of a chestnut brown hue. A prominent nose stands over his large mouth, that wears a pleasant smile and is supported by a broad prominent chin. His skin is white and the whole is illuminated with the bright clear light of his grayish-blue eyes, that wear an animated expression in conversation. His manner is quiet and unostentatious; exhibiting none of that egotistical assurance that might be looked for, in a man who has so much of which to be justly proud. Mr. Edison might justly be styled, the Newton of the present day. He seems to have been born to harness and control that most potent of all forces, in the world of matter—Electricity. As a telegraph boy in a Tennessee office, he was so persistent in experimenting with the instruments and wires, that the principal discharged him from the office. But such was the fascination of the power of Electricity, that he put his whole life into its study, and ere long was the only man that could be found who could receive unbroken dispatches in a Boston office, from a noted operator in New York. His has been continually experimenting and inventing electrical machines; and now at the age of thirty two, he has taken out one hundred and seventy seven patents.

He resides at Menlo Park, New Jersey, where he has a laboratory and workshops, in which he has more than thirty men engaged in working out his ideas. The Telephone has been perfected already a year; but there are two reasons why they are not more generally known; one is that in explaining such things, scientific men use so many technical terms and uncommon expressions, that the ordinary reader cannot put the parts together to make a perfect whole; and another is, that the Western Union Telegraph Company, seeing its offspring, fearing that its general utility would destroy their immense business, leased the proprietorship of the Telephone for a term of years; and as they do not yet care to have it in general use, there has been no one to make a noise about it. And yet, there are more of them used on private lines than is generally supposed. The instrument consists of a mouth piece on iron disk or diaphragm and a delicately balanced bar with a platinum

TOLEDO BLADE.

WEDNESDAY EVENING, MAY 15.

THE PHONOGRAPH.

First Appearance of this Wonderful Invention in Toledo—A test at the Boody House last Evening—Wonderful Performances "et then Machine that is creating such a furorp in the scientific world.

Last evening a number of invited guests assembled in room No. 125, Boody House, to inspect the practical workings of Edison's Phonograph, the first one introduced in Ohio. The machine was exhibited by Mr. A. D. White, a gentleman well known to Toledoans and one in whose hands the machine was displayed to its best advantage.

On a table in front of about thirty ladies and gentlemen was a little oblong machine, the first, prominent feature of which is a little black mouthpiece, over a finely grooved steel cylinder, which is turned by a small crank at the end. After a brief inspection of the phonograph, the practical test began. Mr. White took a piece of bright tin foil, about the size of a sheet of note paper, placed it on the steel cylinder, the edge being long enough to just go around. Then, putting his mouth close to the mouthpiece, and turning the crank slowly with his right hand, Mr. White recited in a clear tone of voice, with great expression, the lines, "Now is the winter of our discontent," &c. These, the machine recited back to him, as he turned until the mouthpiece was directly over the starting point, and then, putting a finger to the mouthpiece, the crank was turned and slowly and distinctly came the words, "Now is the winter of our discontent, made glorious summer by this sun of York," every syllable just as Mr. White had spoken it, with the same inflections and peculiarities of voice reproduced exactly.

The effect was wonderful, and every one present declared that the phonograph was a marvelous invention. Then followed another inspection of the talking machine, the examination and trial being eagerly solicited by attendants. As the machine is thrown into the air as other could produce such results. There was a little piece of sensitive vellum, such as photographers use in taking the types. Back of this, connected with the frame by a small steel spring, was a diminutive piece of black rubber battery. On the plate this material was laying on the surface of a piece of steel, and about one-fourth of a square inch and about one-fourth its length. This needle passing along the grooves, over the tin foil on the cylinder is the cause of all the noise. As the voice is thrown into the mouthpiece it makes sound waves, which strike the tin foil, causing it to vibrate in accordance. The finest little indentations, scarcely perceptible to the eye. Then when the crank is turned again, the pin drops into these holes, agitating the disc or diaphragm, and making again the same sound waves, and consequently reproducing the same sounds. It sound almost impossible that a small piece of paper, a mouthpiece and steel, and diaphragm of soft iron, can speak, just as well as a man, and in fact reproduce, precisely, any sound that may be uttered. Yet the audience last evening was most fully convinced that such was the case.

Mr. Carrier, who had by request brought his organ with him, played a number of familiar airs upon it, the instrument into a manner recorded upon the mouth-piece. A few turns on the crank and the same tunes were heard again, each note, the runs, trills and even a false note purposely played, sounding with clear and distinct and plainly audible tone from the machine. A conversation in a natural manner was carried on, and the phonographic record of it in the most astonishing manner. In fact every conceivable test was made, and the machine was found to be there every time.

The principle of the foil has been found which has been adopted grooves, it is removed and the tin foil is placed in the cylinder. Any desired records may be obtained and preserved for hundreds of years. By placing them on a Phonograph at any time the conversation, music or poem, will be reproduced in exactly the same manner as when the record was made. When one stops to think in what a wonderful extreme this thing can be carried, it is almost incredible to what the inventor had never been born.

The Phonograph exhibited by Mr. White is the first one brought to Ohio, and he has the exclusive right of exhibiting the machines in this section of country. He rooms at 115 Summit Street, over Reuwe's book store, will be thronged to curious people anxious to see or hear, or witness the wonders of the talking machine, the marvel of the nineteenth century. The agents have secured a large number of engagements already in the towns of Northern Ohio, for he is well known and popular, and with his entertainment must of great interest as an actor, his dealings will always prompt and reliable, and as he has a very pleasant association to relate to the Phonograph, his audiences will always be entertaining and instructive. This evening there will be a private exhibition of the machine, and other interesting features.

Week Daily Bee, May 21

Edison's Speaking Phonograph.

AT SAALE HALL, MAY 21, 22, 23,

THREE EXHIBITIONS DAILY,

Commencing Tuesday, May 21st, 1878

Washington Capital, May 16, 1878

THE phonograph is coming and Washingtonians will soon have an opportunity of hearing Mr. Tyndall cuss "the mercy of the century."

EDISON'S SPEAKING PHONOGRAPH

TALKS, LAUGHS, SINGS, PLAYS CORNET SOLOS AND RECITES ANYTHING ALL MANNER OF SOUNDS.

Exhibited at Saale Hall, Washington, MAY 21 TO 23 inclusive.

Thursday evening, May 23d, at 8 o'clock.

NEWARK DAILY ADVERTISER.

MONDAY EVENING, MAY 20, 1878.

Mr. Edison, who, it will be remembered, is somewhat deaf, writes to a Boston gentleman that he has invented a new diaphragm which, attached to his ear, will so gather and concentrate sound vibrations as to enable him to hear ordinary conversation. Should even that of the drumming of the telegraph instrument in the future so apply its to the phonograph, so that speeches or debates may be registered at a distance from the speaker. At present one may apply it to his ear in a public assembly and catch the words of a speaker at an almost incredible distance.

HOW EDISON AMUSES HIMSELF.

Cincinnati Saturday Night.

Edison, the telegraph man, is watched until he leaves half a dozen things every day. He doesn't look for mementos when engaged in business that's pressing. The other day he went out to the middle stroll and he thought out a plan for working on one key so as to rest the other, before he knew it he was there.

He lolled a little more and told the driver of a little invisible thought and passed through his head just that moment for delivering milk without getting out of his wagon or even stopping his horses. A simple screw-pump, with hose attached, worked by the milk would do the business. Milk-men who desire to halt for anything in their mad career, because they see them running over so many children as they might otherwise do, would appreciate this invention muchly. Here's sure but that messages and "sic" text could be delivered in the same way.

He stepped into a hotel office, and, observing the humiliations which guests encountered in order to obtain information from the Mahlstead desk, he sat down in the reading-room, and in a few moments had invented a device by which for machinery, warranted to stand behind the counter any knight of time desired, and answer all questions with promptness, correctness and gentlemanly demeanor, pick on and hair carried for a reasonable price.

Leaving the hotel-keeper, he was struck with the needless amount of cushions required in each coupe. Edison is fortunate; he thought of a better and more economical plan—sold it the Lake Shore Company, retired on a pretty cord and went to Washington aspiring for a career.

Catching a mint julip in the saloon adjoining, a brilliant idea flashed through his fertile brain, and he immediately set to work to invent an instrument that is likely to revolutionize the entire saloon business. It is a contrivance so attached that when a person has had just been partaking of some nutritious beverage beaten eggs and cream he would receive a peculiarly electrical sensation from the invention of Mr. Edison) made to revolve a small brush over a small comb, rather on an intermission, that by again applying the lips and turning the crank the person could have another of cream cobs. Edison continued his walk to Pennsylvania, and the saloons will be supplied with it shortly, as it would be useless to deprive the business of ninety-nine out of one hundred customers. Edison can mix his drinks just as well, himself, and then stock his telegraph key with a supply of beaten eggs and cream, unless he has lost a finger.

Edison is a genius, and seems to be no donor himself to death with it. He chiefly uses on the instrument not occasionally and never under recollections of their torrent by forming the crank and guide, a waist of the old man's breath.

A capital sensator the telegraph would be to the temperance cause. Often, where husbands are ready to say "don't drink, could have one ready to say "don't drink, could have one ready to say "don't drink, could have bone into at night. The wife, when they come home, could touch the key and say "Mary Jane, please reformation," and also be determined by it. And how every instance the fraudulent husband would be brought to it, it would be never of use to him to say "this is quarter at a mile of one.

When Edison arrived to go out he had to pass the barber-shop of the hotel, and as he was shaved he talked to them, with all his genius for invention, a suggestion, he could never keep so quiet that he could not hear a talking-machine. The suddenly he saw that his work done and wanted no more that day.

THE DAILY CRITIC.

Established August, 1868.

Saturday, May 18, 1878.

A CUE FOR THE ADMIRONDE.—We are, to-day discussed chiefly the dangerous of English commerce in view of Russia's preparations to assail it, and in the course of our article spoke of fleets of merchantmen selling under convoy of armed vessels. From ex port like New York, it would not be difficult for several steamers or for a number of sailing vessels to start at the same time and to keep so near together, under ordinary circumstances, that each one of them might always be in sight of one or more of the others and that a chain of communication might be maintained between them. In this connection Edison's invention for the augmentation of sound may possibly be put to so important, practical use. If an outgoing vessel found herself approached by a suspicious craft, the aeroplane could be used to communicate the fact to her nearest consort, and the word could be passed from one to another until it reached one or more of the armed vessels. The threatened merchantman could be told which way to steer for protection, and the man of war could be apprised of the quarter in which succor was needed. For additional security a countersign could be agreed upon before sailing, or the vessel would assist sight in enabling the companion ships to identify each other.

AMUSEMENTS.

The Edison Phonograph.

The first public exhibition in Edison's phonograph was given in the lower hall of Masonic Temple yesterday, and a large number of persons were in attendance. The instrument has already been described in these columns, and it is unnecessary further to speak of its appearance. In fact, the looking-at now nothing but a cylinder resting on a shaft, and a small mouthpiece into which the operator speaks, and which is connected with a diaphragm. By means of the cylinder the sounds impressed upon it are made with wonderful distinctness, and the machine will repeat them many hundred times. They will be heard with equal force, and the operator was told that at the last exhibition in Washington over one thousand persons had successively listened to the instrument without causing any injury to the cylinder. Mr. Edison's invention for the augmentation of sound may possibly be put to so important, practical use. If an outgoing vessel found herself approached by a suspicious craft, the aeroplane could be used to communicate the fact to her nearest consort, and the word could be passed from one to another until it reached one or more of the armed vessels. The threatened merchantman could be told which way to steer for protection, and the man of war could be apprised of the quarter in which succor was needed. For additional security a countersign could be agreed upon before sailing, or the vessel would assist sight in enabling the companion ships to identify each other.

VISITING MR. EDISON.

WHAT A PARTY SAW AND HEARD—PHONOGRAPH, TELEPHONE, ETC.

A day or two ago a party left Jersey City with the avowed purpose of visiting the laboratory of the great electrician, Mr. Edison, at Menlo Park. Among the party were Mr. Charles Watts, assistant superintendent of the New York Division of the Pennsylvania Railroad, and his accomplished wife, Mrs. Gilchrist, of New York; Mr. Wm. Eldner, division operator of the New York Division; Mr. R. A. Shultz and wife, Mr. A. S. Dahl, general manager of the D. Y. Transfer Co., Mr. Wolverton, President of the Company, Mr. B. F. Thorne, Mr. H. C. Rue, Col. Rose, Mr. Richards, a JOURNAL reporter and others. For the time thus the party arrived at Menlo Park, a small station just this side of Metuchen, and clambered up the hillside on the right of the road. On the summit of the hill a brick house was blowing, which invigorated the sight-seers amazingly. They struggled over the sprout field, cheering and laughing gaily. Across the field was a long, two-story frame building, with a big shed-like mounting guard on the piazza. Whether the numerical strength of the party awed the dog, or whether he was dead natured, was not known at first. He offered no objections to the ingress of the party. As soon as the party entered the building they ascended the stairs and at once surrounded a brown with cheerful gentleness, who sat at a bench like a carpenter's bench with a brass cylinder in front of him. The green coon thought it was Mr. Edison, and were about to make their salaam to the great inventor, when Mr. Ettinger remarked, "Mr. Bitchelor, allow me to introduce some of my friends." Mr. Bitchelor bowed politely, and that Mr. Edison was away on business, and turned at once to the cylinder. It was about a foot long and five inches in diameter, and worked from left to right, and back again by means of a screw shaft, worked by a belt and gearing attached to steam power beneath the table. In front of Mr. Bitchelor and between him and the cylinder was a little round piece of wood, disk-shaped, with a hole in the middle. On the sides of the wooden disk, opposite Mr. Bitchelor and nearest the cylinder was attached a disk of metal with a point in the middle of it. This Mr. B. said was a diaphragm, and every person present thought of the sensitive instrument which has been the purchase of their interest in a sewing machine. He put on a sheet of tinfoil six inches wide and ten inches long, and put it around the cylinder, pasting the ends together thus making a band of tinfoil. The cylinder was then fitted with groves an eighth of an inch apart, and Mr. Bitchelor put the point of the metal in the diaphragm against the tinfoil, in one of the grooves and started his machine. Then he began and into the little hole of the wooden disk, "Mary had a little lamb," and turned the crank for one or two on all the way through, the little point ran back to the beginning of the groove and the cylinder, and it moved up and down against the tin foil, making little indentations in it. When he got to the end of the words returning to Mary and her lamb, Mr. B. pulled the wooden disk with it back in a way, stopped the cylinder and put the point of the metal in the groove the plate. Started from, he put the point of the diaphragm against the tin foil, gazing it fit to fit the indentations it made. Then he placed the apex of a paper cone in the hole in the wooden disk, and the small end he inserted the machine again, then turned the crank long the words, "Mary had a little lamb, &c.," and sure enough, the first they could be heard all over the room. It was a grave ay moment to the green coon. That's all there is about the phonograph. Its simplicity is astonishing. It is a toy, but a wonderful toy. Mr. Edison has given to the world a ghost of toy, and made the ingenious public on the discovery. After the intended case of the seeing was over the boys in the evening club, "Old Uncle Nat." This he repeated, and from set the point of the metal in the groove, and turning the crank started the machine again, thus:

"Mary had a little lamb," &c. Running the New York Division of the Pennsylvania Railroad, and his accomplished wife, Mrs. Gilchrist, of New York; Mr. Wm. Eldner, division operator of the New York Division; Mr. R. A. Shultz and wife, Mr. A. S. Dahl, general manager of the D. Y. Transfer Co., Mr. Wolverton, President of the Company, Mr. B. F. Thorne, Mr. H. C. Rue, Col. Rose, Mr. Richards, a JOURNAL reporter and others. For the time thus the party arrived at Menlo Park, a small station just this side of Metuchen, and clambered up the hillside on the right of the road. On the sum-

The Daily Graphic
THURSDAY, MAY 16, 1878.

THE BIRTH OF THE PHONOGRAPH.

I read from this week's Graphic the following account of the birth of the Phonograph, which is interesting as showing the manner in which inventions are brought forth. Mr. Edison is represented as having a working model of the machine, and he only has to perfect it. But the Phonograph is not a machine, and Mr. Edison has not got a working model. He has got a piece of tinfoil, which will receive impressions, and which will reproduce them once or twice. The machine which will do this has yet to be invented, and Mr. Edison has yet to invent it. He has not the slightest conception of what form it will take, or of what principle it will be based upon. He has not even decided whether it will be worked by steam, by electricity, by clockwork, or by hand. He has not even decided whether it will be a machine at all, or whether it will be a delicate instrument, like a watch. He has not even decided whether it will be large or small. He has not even decided whether it will be expensive or cheap. He has not even decided whether it will be simple or complex. He has not even decided whether it will be useful or useless. He has not even decided whether it will be a success or a failure. He has not even decided whether it will be anything at all. He has not even decided whether it will be anything else. He has not even decided whether it will be anything whatever. He has not even decided whether it will be anything in the world. He has not even decided whether it will be anything in the universe. He has not even decided whether it will be anything in the multiverse. He has not even decided whether it will be anything in the omniverse. He has not even decided whether it will be anything in the pluriverse. He has not even decided whether it will be anything in the infinite. He has not even decided whether it will be anything in the eternal. He has not even decided whether it will be anything in the absolute. He has not even decided whether it will be anything in the relative. He has not even decided whether it will be anything in the subjective. He has not even decided whether it will be anything in the objective. He has not even decided whether it will be anything in the noumenal. He has not even decided whether it will be anything in the phenomenal. He has not even decided whether it will be anything in the transcendental. He has not even decided whether it will be anything in the immanent. He has not even decided whether it will be anything in the metaphysical. He has not even decided whether it will be anything in the physical. He has not even decided whether it will be anything in the psychological. He has not even decided whether it will be anything in the ontological. He has not even decided whether it will be anything in the cosmological. He has not even decided whether it will be anything in the theological. He has not even decided whether it will be anything in the anthropological. He has not even decided whether it will be anything in the sociological. He has not even decided whether it will be anything in the political. He has not even decided whether it will be anything in the economical. He has not even decided whether it will be anything in the financial. He has not even decided whether it will be anything in the commercial. He has not even decided whether it will be anything in the industrial. He has not even decided whether it will be anything in the agricultural. He has not even decided whether it will be anything in the horticultural. He has not even decided whether it will be anything in the floricultural. He has not even decided whether it will be anything in the arboricultural. He has not even decided whether it will be anything in the viticultural. He has not even decided whether it will be anything in the pomological. He has not even decided whether it will be anything in the olericultural. He has not even decided whether it will be anything in the apicultural. He has not even decided whether it will be anything in the aviculturalist. He has not even decided whether it will be anything in the piscicultural. He has not even decided whether it will be anything in the conchological. He has not even decided whether it will be anything in the entomological. He has not even decided whether it will be anything in the herpetological. He has not even decided whether it will be anything in the ornithological. He has not even decided whether it will be anything in the mammalogical. He has not even decided whether it will be anything in the primatological. He has not even decided whether it will be anything in the anthropological. He has not even decided whether it will be anything in the ethnological. He has not even decided whether it will be anything in the philological. He has not even decided whether it will be anything in the archæological. He has not even decided whether it will be anything in the historical. He has not even decided whether it will be anything in the biographical. He has not even decided whether it will be anything in the autobiographical. He has not even decided whether it will be anything in the geographical. He has not even decided whether it will be anything in the topographical. He has not even decided whether it will be anything in the cartographical. He has not even decided whether it will be anything in the geological. He has not even decided whether it will be anything in the mineralogical. He has not even decided whether it will be anything in the crystallographical. He has not even decided whether it will be anything in the petrological. He has not even decided whether it will be anything in the paleontological. He has not even decided whether it will be anything in the zoological. He has not even decided whether it will be anything in the botanical. He has not even decided whether it will be anything in the physiological. He has not even decided whether it will be anything in the pathological. He has not even decided whether it will be anything in the therapeutical. He has not even decided whether it will be anything in the hygienic. He has not even decided whether it will be anything in the dietetic. He has not even decided whether it will be anything in the pugilistic. He has not even decided whether it will be anything in the equestrian. He has not even decided whether it will be anything in the aquatic. He has not even decided whether it will be anything in the nautical. He has not even decided whether it will be anything in the aeronautical. He has not even decided whether it will be anything in the astronautical. He has not even decided whether it will be anything in the cometary. He has not even decided whether it will be anything in the planetary. He has not even decided whether it will be anything in the solar. He has not even decided whether it will be anything in the stellar. He has not even decided whether it will be anything in the nebular. He has not even decided whether it will be anything in the galactic. He has not even decided whether it will be anything in the sidereal. He has not even decided whether it will be anything in the universal. He has not even decided whether it will be anything in the multiversal. He has not even decided whether it will be anything in the omniversal. He has not even decided whether it will be anything in the pluriversal

64

In Goodwin's edition of Plutarch's Morals, vol. II, p. 466, in the essay, How a Man May be Sensible of his Progress in Virtue, we find the following:

This Antiphanes said merrily, that in a certain city the cold was so intense that words were congealed as soon as spoken, but after some time they thawed and began to come audible, so that the words spoken in winter were articulated next summer. Even so the many excellent precepts of Plato, which he published like the best coiners of his scholars, were scarcely understood and distinguished by many of those till they grew more and mellow'd the warm, vigorous summer of their age.

The original thought, it will be seen, is the best, and the application has a rare and poetic beauty.

Mad, do Stael, in Corinne, speaks of a monument as music forever, and Schilling said "Architecture is music in space, as it were, a frozen music."

So this thought has been circulating two thousand years or more, and Edison comes along and makes it an every day reality. He is called an inventor, while Manchanan was only a liar. The two are closely allied, the poet being their head of union. The new world in the West was the dream of a Latin poet but a reality with Columbus.

Chicago Tribune
May 21

THE PHONOGRAPH.

To the Editor of The Tribune.

GROVE'S LAKE, Wis., May 18.—The continued criticism of Mr. George B. Ives of the article on the phonograph I cheerfully accept. What is wanted is more and not perfect sense cannot be produced. My suggestions were based on the statement "that sounds are produced by purely mechanical force." I may be mistaken in supposing that this statement tegenerally believed, but would ask, however, was the effect produced by the phonograph be the result of waves, merely mechanical, of either air or ether?

I would now present my ideas in the form of queries, which would enable me to state the case with which would enable me to state as facts that which has been proved as truth by my critics.

1. Is there any reason why the diaphragm, vibrating in contact with the sharply defined edge of an excitrol current which conveys the sound in a telephone, will not produce sound?

The sound waves striking over indentations "to assist that they cause the diaphragm to vibrate with the effect of the same continuous vibrations of the diaphragm in the tele?

Does not the exhaustion of the electrical current produce the effect?

At set in motion cause the force, which is conveyed by the electric current to the receiver, and even "through the same force" produce the sound of the human voice. Cannot the force be conveyed by the electric current, air, or with a current of air, be made to produce sudden vibrations of the disk, producing sound?

When the phonographic sentences has been made over the phonograph, a subsequent record may be made over the first, and the first record will be reproduced at the same time, although less "sonic contrast, and a slight interference of the two records would be noted by adapting the proper receiver.

What the point first passes over the tin-foil an indentation is made, and the diaphragm, in passing over it the second time, will vibrate. By reading of the disk, a second connection is made, and the diaphragm is caused to vibrate. Thus, when the disk is spun and reversed, the same takes up and conveys both sounds at once.

Are not the workings of the phonograph and telephone on the same principle, involving identical motion?

Chicago Tribune
May 16

THE WONDERS OF THE PHONOGRAPH.

To the Editor of The Tribune.

CHICAGO, May 15.—In your paper of the 10th inst., "C." and George Lake, Wis., signing themselves, or Mr. Edison has not been practicing upon the credulity of the public by means of ventriloquism when exhibiting his phonograph.

Edison have a scientific fraud.

Your correspondent cannot have examined the evidence carefully or he would not have ventured upon such an insinuation.

Fortunately, the results accomplished with the phonograph do not now rest upon the testimony of Edison alone, nor upon his manipulation of the machine.

The successful exhibition of the first phonograph in this city was described in the columns of the *Scientific American*, which has repeatedly indorsed all that has thus far been claimed for the machine.

Favorable notices of all the New York papers, and others from other localities, have examined the phonograph, and have given their opinions as to its merits. Elaborate descriptions and indorsements have been printed in the leading periodicals. Many scientists have personally tested the phonograph to their entire satisfaction.

The phonograph has been exhibited to the leading scientific societies in the United States, Scotland, and France, and they have passed resolutions of thanks to the inventor. There are now in this city several machines in existence in the hands of different parties, and in this country, and it is daily exhibited in New York.

At least Edison people have seen and listened to the performances.

Mr. Edison has nothing to do with these exhibitions. He is at present fully occupied in his laboratory at Menlo Park, N. J., where he is preparing to be said, and even when in the room Edison upon deception; but all have a chance to examine for themselves until perfectly satisfied.

Mr. Edison has used the phonograph on several occasions. His words, spoken in a tone lower than ordinary conversation, have been accurately recorded and reproduced.

He has heard the phonograph talk, laugh and sing, and whistle.

It reproduces the sounds perfectly.

The words, tones, and inflections upon disks are being taken in an accurately manner.

When a sentence has been spoken to the phonograph, the record is removed, and the needle over the first, and the two utterances will be reproduced at the same time. Sometimes there is some confusion and a slight indistinctness.

A few simple experiments will satisfy any one as to the nature of the work.

Place a silk hat, and, placing one hand upon the crown, speak into the opening towards the bottom. The vibrations of the sound of the crown of the hat correspond to the movements of the phonograph's dial.

Place the hand on a glass or thin board while talking, and the effect will be noted. The vibration of the partition will be plainly felt.

3. Listen in a room separated by a brick partition from another in which a loud conversation is being carried on. Much that is said will be heard distinctly, and this can only be by the vibrations of the wall. In one room being imparted to the wall there, which are imparted then to the air in the next room.

Words, spoken with a powerful voice, will frequently cause the phonograph needle through its disk.

So delicate is the instrument that intelligible sounds will be made when the voice vibrates the disk and give out the original sound.

It is not strange that there should be some inaccuracy relative to the performances of such a wonderful instrument, especially when it performs the functions of the complicated mechanism by the human body.

There has probably never been an important invention made available for practical use in which there was not, thus as will be the case with the phonograph.

It is necessary, however, that a standard machine as near perfection as possible in all its details should be made before general introduction. Then the owning phonographs will be able to use them for communicating with each other, which could not be done if the machines were different. At present, the records made on a phonograph cannot be used after reproduction.

Mr. Edison's time is fully occupied in his method.

To perfect the phonograph will require some weeks yet. In the meantime, the Phonograph Company proposes to exhibit the machine as it now is in the various parts of the country.

If the public will possess a little patience for a short time, Edison will be able to vex the ear and tear and hear with their own ears what the phonograph can do.

GEORGE H. BLISS.

THE DAILY GRAPHIC

TUESDAY, MAY 21, 1878.

—Edison's "apparatus for the deaf," the New Haven *Register* says, "will enable them to denominate time to walking on railroad tracks."

Commercial Advertiser.

TUESDAY AFTERNOON, MAY 21, 1878.

The latest invention of Mr. Edison is a machine to rock a cradle. When the baby cries the sound is received by a telephone, which, operating through a battery and magnets, sets in motion a lever which rocks the cradle. This was done on the spur of the moment, and was the answer to a challenge.—*Rochester Express.*

MR. EDISON'S RECEPTION.

THE "WONDERFUL" HAVING GIVEN A PARTY, IT WAS MEET TO FIND HIS SHOP INVADED.

LADIES ASTONISHED AT BEING OUR TALKED AND PLEASED WITH A DEVICE FOR QUIETING THE BABY.

Mr. Bayard Taylor, now Minister to Germany, (in his novel of "Hannah Thurston," described his hero as styling an evening party "a large, bare room, lighted by candles, the hare, being poverty-stricken. A second visit whether occurred last night at the wonderful Edison's laboratory at Menlo Park, the difference being that Mr. Edison, thanks to his inventions, is not poor, and that the "evening" was opened by one of Mr. Edison's own contrivances. Mr. J. W. Tower, reporter of the *Scientific American*, had with the visitor's permission, arranged for a sort of reception to the phonograph, and Private Secretary Ash New York at 4 p.m. to invite a few friends to witness it. Among those who were W. W. Rossa, the well-known poet; Gen. Gilmore, U. S. Engs. Dr. Hahn, Henry H. Benn, of the New Jersey Mutual, J. W. McCulloh, agent, of the New York Associated Press, Mr. Bonelli, of the Telegraph Company; Clark Wargrave, Colonel of Internal Revenue at Toledo, and his son G. B. Mc. engineer of the Department of Docks; Mr. Sarony, Jacob Craig and Winslow Judson, of the Fifth Avenue Hotel; Edward Bleecker, Albert Weber, W. D. Sloak, a prominent engineer, and Mrs. White, of Brooklyn, with several other ladies.

It was strange that a reception should be held in a workshop, but Mr. Edison did not mind this fact, as he was busily engaged with some new idea when his guests arrived, and the latter made no complaint, as they were only too anxious to hear the phonograph. Mr. Bleecker, Mr. Edison's accomplished fiancée, and Mrs. Edison were the upper floor, and the ladies and gentlemen were left to themselves somewhat. Gen. Gilmore, always about the instrument, to add that they had heard a good deal about it, but that they had never seen it, and he intended to write to all his scientific friends and tell their they should go.

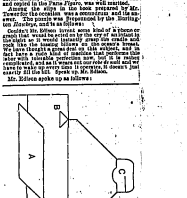
Then Mr. Bleecker took his seat before Mr. Edison's harp, as he called it, and sang, whistled and played on the violin, the machine reproducing "Mary's little lamb." Soon Mr. Edison was called for, and, with a look of mischief on the fact there was an evening party in his shop, he went up stairs and was heard to say, "Hannah Thurston, I'll be with you again." The proceeding called for a protest from Mr. Weber, and Mr. Edison and Mr. Bleecker then came down stairs, and the latter sang a song which sounded more than usual well. Mr. Ash was on an adjacent table.

"Now we march," said Mr. Cornish, of Cornish's Tavern, who dined with Edison on Saturday last, "to the tune of 'Yankee Doodle.'" "Hello, Ash," said Mr. Edison, "I'll be with you in two minutes." Then Mr. Tower produced a confidential container of a telephonic interchange between Edison and Ash, and read it to the astonishment of the company, that is to say, of "the wonderful Edison," confirmed upon him by THE WORLD and reported in the Tribune and Commercial.

Mr. Edison then set up the tone produced by Mr. Tower for the occasion was a concentrator and the assembly *Rondeau*, and he as follows:

"I have a little machine here, some kind of a thing or other that I had to send to the city of Washington to the other day. It would instantly grasp the cradle and rock it. It is a very simple affair, and I will show it to you. We have brought a great deal of this machinery, and in fact have a clock kind of machine that performs this work. It is a very simple affair, and I will show it to you in a moment, as I have not the rocker at hand and we have to make up every time it operates, it doesn't just exactly fit the bill. Speak to Mr. Edison.

Mr. Edison spoke up as follows:



A. Cradle.
B. Telephone.
C. Battery.
D. Wires, connecting magnets and connected with lever.
E. Weight, attached to lever.

The baby's cradle is to be moved by the telephone, which, when it receives the "music" and machine, sets in motion the lever, which rocks the cradle. When the baby ceases crying, the cradle is still.

After this there was nothing left for the guests to do but to wend their way out of their shop. Mr. Edison having disappeared, as they wended their way to the railway station.

N.Y. Evening Telegram
May 20, 1878

—Now that the phonograph makes it possible for sounds to be saved by the telephone, why not lobsters, fish, &c., whereupon sentence can be heralded and sent on the fresh fish to the table, ready for the table, instead of the inanimate article.

—Do you want to make a sound investment? Then buy a telephone.

Nuove modificazioni al telefono. *Nota di* Bufquar. — Queste modificazioni sono dei signori Garnier e Pollard, ingegneri delle costruzioni navali a Cherbourg.

Una piccola lamina di latta, affatto analoga a quella del telefono Bell, è posta in contatto colla estremità terminante in punta di un lapis ordinario di grafite, e preme leggermente sulla parte centrale di essa lamina.

Il lapis da una parte, la lamina dall'altra sono, con due fili di linea ordinarii, in comunicazione coi due capi del filo del reochetto del telefono Bell, nel quale la calamita è rimpiazzata da un cilindro di ferro dolce. Una pila di dieci elementi Leclanché è interposta nel circuito.

Quando parlando si fa vibrare la lamina dell'apparecchio trasmettitore, l'estremità del lapis di grafite subisce una serie di modificazioni nel suo contatto colla lamina, senzachè per questo il contatto venga interrotto. Queste modificazioni danno luogo nel punto di contatto a variazioni nella resistenza del circuito, e per conseguenza a variazioni nell'intensità della corrente permanente della pila. È chiaro allora che questa corrente, la cui intensità varia coi movimenti elementari della lamina vibrante, produrrà, nell'elettromagnete del telefono ricevitore, delle alternative di attrazione e di non-attrazione. Queste alternative agiscono assolutamente come nell'apparecchio Bell, e permettono in conseguenza d'intendere la voce di una persona che da lontano parla nel trasmettitore. Noi crediamo che questi esperimentatori si avviano sopra un studi che potrà condurli ad un accrescimento d'intensità della voce, quale si ha ora dai telefoni ordinarii. (*Les Mondes.*)

PROFESSOR JOSEPH HENRY.

The death of Professor Henry calls forth numerous tributes of deserved respect and regret. An eminent scientist himself, he probably did as much if not more than any other man to organize and forward scientific studies and research in the United States. Professor Agassiz had a contagious enthusiasm which made him more of a kindling and inspiring personal force in science than Professor Henry, who, though dignified and cautious and kind, somewhat lacked personal magnetism. He was very conservative and cautious, and his attainments were overshadowed by the achievements of men who had more popular gifts and the audacity to launch their combinations as demonstrated conclusions. He shrank from the sharp antagonisms in which so many scientists delight, and leaving them to fight the battles over contested theories of evolution and similar questions, pursued his own studies in quiet, and acted as a peacemaker rather than as a disturber of the peace. A religious man himself, he had such profound faith in religion that he could not believe its bases were shaken or undermined, he even likely to be, however they were assailed; and he deprecated the discussions which were calculated to weaken the faith of any in the religious ideas which he felt were as firmly established as any truths of science. His disinterested devotion to science, refusal to use his knowledge or discoveries for his own personal enrichment, contented to be poor while so many savants were rewarded as well as honored, deserves special notice. Last year, a few gentlemen, knowing how he had labored for science, and had built up an institution which is a real credit to the country, without saving a dollar for himself, subscribed a thousand dollars each, and gave him $40,000 as their tribute to his long life-service. He was overcome by the munificent act, and his modesty and diffidence in accepting the gift were almost child-like. America has few salient examples of the same rank as some European savants, whose fame is world-wide. But Professor Tyndall when here spoke in high terms not only of this great number of men of this power and great promise who are engaged in scientific pursuits, but also of the great mental and high European tone of many of the men who are not deservedly honored by our people, and among them he placed Professor Henry. The honor of such a life as his was in the being of it, and the institution he founded did so much to establish is his monument.

SUNDAY EDITION. ATLT

Edison's Telephone.

New York Correspondence Cincinnati Commercial.

The city telegraph station is to undergo a change which is a revolution. Edison's telephone is the instrument. A meeting of telephonic stock is to be called immediately at the City-Hall and directors elected. Then the manager at the centre will connect and disconnect those wires according to call. For instance, Smith, who owns or hires a telephone, calls for No. 7, who has a telephone; the manager looks for the connection between the two parties, makes a secret circuit, without any assistance, and with no danger of being overheard by any third parties. The revolution is complete. And as every one who has a telephone will, for a merely nominal sum, be able to have interviews, the element of convenience will be very great. Those who have telephones in their houses or offices will have the benefit of public telephones or resort to the slow mercantile delivery of dispatches at present prevailing.

I may add here that the Western Union Company will add to its 7,500 offices at least half as many more during the next year, the extra facilities being rendered necessary by the telegraph service now in use. As there are too many underwriters to pay the dividends on the stock, the new communications will be by telephone. A mouthpiece will hang down from the counter, and receivers will be at the ears of the operators, and every one who wishes to send a message will talk it into the mouthpiece himself. The most enormous will soon be reduced on a large scale, and Mr. Orton, the new President of the Western Union, has lucidly confidence in the practicability.

THE PHONOGRAPH IN LAST DEVICE.

ENGAGEMENTS BOOKED FOR A LECTURE-TOUR THROUGHOUT THE COUNTRY.

At the office of the Phonograph Company, No. 203 Broadway, there are now many persons engaged in issuing the act of incorporating the latest articles. Twenty-two legislators were even yesterday detected by a Times reporter in the act of declaiming at the top of their voices into the mouths of the machines, so that no hour while so many were present at the office. Edison was interviewed all over the United States. Edison's plan investigated.

It seems that the Phonograph Company have been for a few days in possession of the secret of reading an accurate impression of electric sounds, and have hit upon the idea of making a tour throughout the country, giving a series of lectures, illustrated by the instrument. Edison's first lecture, delivered at the Academy of Music, netted a thousand dollars cash, and gave him $40,000 as their tribute to his long life-service. He was overcome by the munificent act, and his modesty and diffidence in accepting the gift were almost child-like. America has few salient examples of the same rank as some European savants, whose fame is world-wide. But Professor Tyndall when here spoke in high terms not only of this great number of men of this power and great promise who are engaged in scientific pursuits, but also of the great mental and high European tone of many of the men who are not deservedly honored by our people, and among them he placed Professor Henry. The honor of such a life as his was in the being of it, and the institution he founded did so much to establish is his monument.

Chicago Tribune
May 14, 1878

From this morning's *Tribune* we learn, that Mr. THOMAS A. EDISON, the phonograph inventor, writes to his acquaintances in Chicago as follows: "I am in New York. I have been here for a few days, many letters, but I only received on the subject of an injunction for the deaf, has overlooked me that I have been in New York. I have been here for a few days, two of my most exciting moments at work testing my inions. I feel sure that I will produce a practical speaking machine."

After Mr. EDISON has succeeded in this great undertaking, he certainly will, we want him to try his hand at an instrument for the deaf and dumb, which will be a blessing to all. We have an eye on him for the fields—dotted and Mindi, which is a word long felt at the *Tribune* office.

NEWARK DAILY ADVERTISER.

FRIDAY EVENING, MAY 17, 1878.

The Telephone in Newark.

The exhibition of the telephone at the Clinton Avenue Congregational Church, last evening, was very satisfactory. The apparatus, though perfectly simple in construction, transmitted messages and vocal and instrumental music in a way that demonstrated the importance of Mr. EDISON'S invention. The great hearing is to be improved in accordance with the suggestions which the audience was so large that the entertainment could not be repeated this evening, with an additional attraction in the shape of an orchestra.

The Phonograph.

Mr. P. L. Leedy exhibited Edison's Phonograph last evening to a select company of gentlemen connected with the press. We have said this to what we have said heretofore. The machine is in its infancy, and great improvements will be essential to bring it into household or common use, but so far it is just from the brain of man, but the mechanical genius of Edison. We will not attempt to describe the wonderful operation of the ingenious one. There is nothing theoretical about it. It is practical, and the time is not far off when it will be in the laboratory of every man who can afford it. Edison's plan investigated.

It seems that the Phonograph Company have been for a few days in possession of the secret of reading an accurate impression of electric sounds, and have hit upon the idea of making a tour throughout the country, giving a series of lectures, illustrated by the instrument. Edison's first lecture, delivered at the Academy of Music, netted a thousand dollars cash, and gave him $40,000 as their tribute to his long life-service. He was overcome by the munificent act, and his modesty and diffidence in accepting the gift were almost child-like. America has few salient examples of the same rank as some European savants, whose fame is world-wide. But Professor Tyndall when here spoke in high terms not only of this great number of men of this power and great promise who are engaged in scientific pursuits, but also of the great mental and high European tone of many of the men who are not deservedly honored by our people, and among them he placed Professor Henry. The honor of such a life as his was in the being of it, and the institution he founded did so much to establish is his monument.

The Alliance.

CHICAGO, SATURDAY, MAY 11, 1878.

THE PHONOGRAPH.

The discovery that the waves of the atmosphere can be caught and reproduced no less than the waves of light is one of the great discoveries in the world. It marks a long step in advance and forms the basis for a strong prediction that the forces of the air will sometime be under man's control. It is a tribute to the strongest argument in proof of a personal Creator, since the machine cannot begin to rival the personality and talking ability even of a child. It proves that man is at the best an imitator and not a creator, for infinitely more wonderful than the phonograph is the meanest shoe-black whom as Carlyle says, even the Lord Mayor of London cannot commission to make lumps, for even a shoe-black is immortal. The phonograph, therefore, rather than an argument for man's creative power, is an argument against it and comes along as a proof that man, in his power of imitating his Creator, is ingenious, but not a formidable rival. Volitions, choices, affections are infinitely more wonderful than the phonograph, but excite less interest because less novel.

But the uses to which the phonograph may be put are of moment in their application to religion for a veritable talking ma-

Edison's Last.

In an interview published in the Washington Post, Mr. EDISON says: "I have a machine in my room now which will record my voice, listen to it in my ears, pronounce it, and, if I am not satisfied with the pronunciation, I can go and put the record back and speak again. I have a new arrangement by which the motor of the machine will run for hours, and I can leave it to itself entirely. It is a curious fact that the words of a speaker almost always sound slow or solemn on the phonograph unless he has not seen it in advance."

The Sun.

THURSDAY, MAY 16, 1878.

Edison's Knot.

In an interview published in the Washington Critic, Mr. Edison declares a marvellous discovery connected with electricity. He says that he has found a new electrical force, which he has named "force," and by which he can transmit messages to any part of the world without wires. He says that he can send a message by this force, and that it will travel around the globe and return to the point from which it started in one-seventh of a second. He says that he can send a message to Europe in this way in one minute and receive the answer in two minutes. He says that he can talk to Europe in this way as easily as he can talk to Washington by the telephone

72

or device to comparative perfection than he hands his highest energies of thought and study to achieve something else—something that might have been successful while improving the former effort.: While off on the new track, however, he does not forget the former work, but is constantly devising such

changes as will advance it towards perfection. The phonograph, or talking machine, was at first the conception of a great idea in a very crude state, and he has worked for its higher development until the new instrument has become a wonder of wonders to all who witness its operations. At first it only spoke in a kind of fantastic falsetto, somewhat difficult to hear; now it gives the volume, tone, inflection, emphasis and brogue, if any, of the voice which speaks through its mouthpiece.

At first this instrument was called a wonderful toy—literally and nothing more. But with the improvements being made, it promises to become one of the most valuable, practical and universally applicable inventions of the age. Connected with improved telephones by the same inventor, it will record messages hour-long distances over the wires, and these messages can reserved and heard to-him by bit one phonograph in his private house, and the other in his office containing them filed away for future reference.

TALKING AND MUSICAL CLOCKS.

The Phonograph and Telephone Company at 203 Broadway, New York, of which E. H. Johnson, Esq., is President, have in charge the manufacture and sale of these instruments. In a pleasant interview with Mr. Chower, one of the directors, he learned that they are got ing up an interesting clock with a phonographic attachment, which shall sing songs or utter words and sentences to suit the taste of the purchaser. This will leave the old-fashion clock quite in the shade, and give even the poor man a chance to have beautiful music in his cottage, warbled in the sweet voice of a Patti or a Nilsson. With such an attachment the Great Master and his twelve Apostles in the famous Strasburg clock might add the words of their faith to the usual hour of an empty parade. But the future possibilities of this marvelous [illegible] cannot be estimated now.

THE SEXTUPLEX TELEGRAPH.

The latest and most wonderful, if not the most practical of Mr. Edison's discoveries, is that of the sextuplex telegraph, by which six different messages are sent over the same wire at the same instant. Think for a moment of what railroads, electricity and Edison are bringing us to; then think of the millennium and be happy.

MUSIC.

IMPROMPTU ON THE TELEPHONE.

Echo used to answer "where?"
In mountain glen or wood,
The prairie never heard its voice
Nor answered laid or good.
Reverberation came from shock
From violent explosion,
Unlike echo it never did mock
By atmospheric motion.
Now the cunning Edison
Has won reverberation,
And coaxes spirit that he has
His it cannot for preservation.
The thrilling tones of melody,
Our discords harshest sound,
In "safety phonograph deposit"
Alike are surely bound.—*Selah.*

THE PHONOGRAPH IN CHURCH.

Organs hereafter will probably be done away with in churches; we mean of course, except in a few instances, for example, that have got new ones, as it is found that by purchasing a large-sized phonograph, with a full stock of prepared tin-foil tunes, or tuneful tin-foils, which embrace a repertoire of the best music of the leading churches, together with the words, singers and organ can be dispensed with. The tones of the organ and music and words of the "*Te Deum*," "Mass" or Hymns, &c., are now readily re-produced and of a startling naturalness and also with sufficient loudness—owing to Prof. Edison's recent invention of the howlophone—to be heard in the most distant corner of a church and arouse the attention even of the deepest slumberer. It has recently been tried, as we learn, at a church in Hoboken, N. J., with eminently satisfactory results, and a company is already formed to furnish churches and other places, with phonographs giving the organ accompaniment and the voices of a quartette, soloists or chorus, either or all, combined or single, in fact, all the musical effects required. "The company (limited), have already pe-fected a number of tin-foil plates which have recorded on them the principal sacred solos, as the services of such singers as Kellogg, Thursby, Cary, Pappenheim, Remmertz, and many others, were engaged long ago to sing into the phonograph so that the demand for "I know that my Redeemer liveth," "On mighty Pens," "It is enough," "*Cujus Animam*," &c., could be supplied to churches *at all* and at once; also a list of pieces and the singers name opposite, so that purchasers can have a choice of singers as well as compositions. We expect soon to hear some of them in our Buffalo churches as the expense is small, not over a few hundred dollars, which will supply a phonograph and also a large number of pieces suited to every phase of the church musical service, and taste of music committees.

In the announcements hereafter given out by our enterprising leaders, organists and "directors." We expect to see something like the following: Next Sunday the "Inflammatus" will be produced as phonographed by Miss Thursby, especially for the church, with full chorus, as given by the choir of the "Old Zebra" of New York. Or, Sullivan's Grand "*Te Deum*" as sung at Crystal Palace, London, phonographed by the London Phonographic Company, and purchased for this church at [illegible] sheet. No more orchestras or pieces of one, in church.

The sad reflection forces itself on us, however, that these little uncomplaining tin foils, that never lose their temper, metalically speaking, and are never jealous of each other, and don't slip out of tune, or wear spring bonnets, &c., may drive out our choirs altogether, and "what will poor Robin do then?" And, horrible thought, perhaps a speaking phonograph may be put in the other end of the church, too, and only good sermons and sound reflections ground out—so to speak—to the assembled congregations. We look for farther and immediate developments in this line, and, we believe, that the great inventor will shortly "send a man" here to demonstrate that both ends of the average church can be better run phonographically, than as at present advised.

[illegible] 1878.

73

Two Hours with Edison.

To the Editor of the Brooklyn Daily Times:

The following is an account of my visit to Mr. Edison's workshop, which, I hope, will be found acceptable to the readers of the Times, for whom it is written.

"Ticket to Menlo Park and return," I said, on entering the office at 6oot of Delaware street, at 2 P. M., last Wednesday.

"Seventy-eight, cents," said the man, "but answered, and in forty minutes I heard the call, "All out for Menlo Park!"

"Where is Mr. Edison's ?" I asked, and a well-behaved boy, fourteen years old, answered, "Up yonder; I work there;" and the boy and I moved forward, followed by those gentlemen who had gone up on the same train, and who, as I soon learned, did not need any guide. They were Mr. Blackman and two other of the principal officials from the office of the Union Telegraph Company, up there to look through and see how matters were progressing.

"Where does Mr. Edison live?" I said to my young guide.

"In that large house beside beyond the trees," said he, "and the shop is over there, on the west side."

"And how large a staff have you here?"

"Office and two dozen—fifty-five and boy—and every one busy as a bee."

"Are there any other bodies around here?" said I, referring to four or five substantial residences: "besides his own."

"The men that work for him."

"Does he employ many of them?"

"Sixteen regular and seven in the office-men and boys."

We had now reached the laboratory, so-called—two large wooden buildings, about thirty by forty feet, set of one side of which steam from the engine house was conducted.

Mr. Edison stood on one at the door, in a manner so frank, kind and cordial, that I would have known him anywhere, even if I had not seen his picture. I handed him a card, which he read, and, as my letter, which he read at a glance, and at the next moment was greeting me as an acquaintance of the Union office. I did not observe in Mr. Edison, either in his manner or appearance, anything that would have differed any from the description I had read of. He is thoroughly devoid of that [illegible] which characterizes the average inventor. He is a little thoughtful when not talking to you, but he is not one. But with this man, whose name and fame are known throughout the world, there is not a trace of self-consciousness. He is as unaffected as a child, clear and distinct, but not very loud; and this you must recollect of the man of whom I am writing. He knows the phonograph, however, and so did we, every one of us.

"I shall make it a point," I said, "to write and tell the folks this afternoon all about, how and better, and I shall tell them that I have seen and heard and shouted to the phonograph, and heard it shout back."

"Never, sir," said Mr. Edison, "never tell them that the talk this afternoon was heard, and that the shouting was heard, for I have been pestered to death with letters from people who have heard of it, and I have not time to answer them."

"I will make it a point to tell them that you have told me that you will not answer letters about it."

"Yes, sir," said Mr. Edison, "I will be much obliged to you if you will do so."

The instrument Mr. Edison had in position, and ready for operating upon, is only eight inches by four—consisting of screws, tin cylinder, made of brass, with steel mandrel, &c. Any one, I found, is to hold to be sound, or transmit the sound, proper to be recorded, and to reproduce it afterward.

The entire process is not short, as the reader may fancy, to-gether. Months of the genius, one sixty-fourth of the royal four sixty-fourths, or one-sixteenth of the whole.

Mr. Edison's laboratory is about three-quarters of the royal four sixty-fourths, or one-sixteenth of an hour's ride from the city.

Both the Times and its advertising agent cannot be spoilt four minutes' fast now, and I would direct the attention of the reader to the fact that the readers here, of every description, are not to be found in the office, but in the department itself; and yet the Times is the only paper that has the full and correct list of many words of the truth, and that up to the hour of going to press.

The Times has more than any one, than one-eighth of all local news, and nearly one-sixteenth of all the news of the world, and more than one-sixteenth of all the news of the world, and more than one-sixteenth of all the news of the world, and more than

"THE TELEPHONE."

FRIDAY.....May17.

Abor'ginals—The Wonderful Possibilities of Edison's Invention.

[*Yhe.A.Ellion in the North Amer.Re'w.*]

Of all the writer's inventions, none has commanded such profound and earnest attention throughout the civilized world as has the phonograph.—This fact is attributed largely to that peculiarity of the invention, which brings its possibilities within the range of the speculative imaginations of all thinking people, as well as to the almost universal applicability of the foundation principles, namely, the gathering up and retaining of sounds hitherto fugitive, and their reproduction at will.

From the very abundance of conjectural and prophetic opinions which have been disseminated by the press, the public is liable to become confused, and less accurately informed as to the immediate result and effects of the phonograph than if the invention had been one confined to certain specific applications, and therefore of less interest to the masses. The writer has no fault to find with this condition of the discussion of the merits and possibilities of his invention; for, indeed, the possibilities are so illimitable and the probabilities so numerous that he—though subject to the influences of familiar contact—is himself in a somewhat elastic condition of mind as to where to draw the dividing line. In point of fact, such line cannot with safety be defined in ordinary inventions at so early a stage in the development. In the case of an invention of the nature and scope of the phonograph, it is practically impossible to indicate it to-day, for to-morrow a trifle may extend it almost indefinitely.

There are, however, certain stages in the developing process which have thus far been actually reached; certain others which are clearly within reach; and others which, though they are in the light of to-day classed as impossible, may to-morrow become probable, and a little later actual achievements. * * *

If the reproduction of sound is to be made audible to an audience, considerable force is requisite in the original utterance; if for his individual use, only the ordinary conversational tone (even a whisper has been reproduced.) In both cases the original utterances are delivered directly in the mouth-piece of the instrument. An audible reproduction may, however, be had by speaking at the instrument from a distance of from two to three feet in a loud tone. The application of a flaring tube or funnel to collect the sound-waves and the construction of an especially delicate diaphragm and embossing point, &c., are the simple means which suggest themselves to effect this. The writer has not as yet given this stage of the development much attention, but sees no practical difficulty in gathering up and retaining a sectional part of the sound-waves diffused about the original source, within a radius of, say three feet, (sufficiently removed not to be annoying to a speaker or a singer.)

The stage of development reached by the several essential features of the phonograph demonstrates the following as *fully accomplish*:

1. The capacity of all manner of sound waves heretofore designated as "fugitive," and their permanent retention.

2. Their reproduction with all their original characteristics at will, without the presence or consent of the original source, and after the lapse of any period of time.

3 The transmission of such captive sounds through the ordinary channels of commercial intercourse and trade in unlimited form, for purposes of communication or as merchantable goods.

4. Indefinite multiplication and preservation of such sounds, without regard to the existence or non-existence of the original source.

5. The application of sounds, with or without the knowledge or consent of the source of their origin.

The probable application of these properties of the phonograph and the various branches of commercial and scientific industry presently indicated will require the exercise of more or less mechanical ingenuity. Conceding that the apparatus is practically perfected in so far as the faithful reproduction of sound is concerned, many of the following applications will be made the moment the new form of apparatus, which the writer is now about completing, is finished. These, then, might be classed as serviceable; but they so closely trench upon other applications which will immediately follow that it is impossible to separate them hence they are all enumerated under the head of probabilities, and each specially considered. Among the more important may be mentioned: *Letter-writing* and other forms of dictation books; phonographic music, family record; and such electrotype publications as books, musical boxes, toys, clock, advertising and signalling apparatus, speaking, &c., &c.

Letter Writing.—The apparatus now being perfected in mechanical details will be the standard phonograph, and may be used for all purposes, except such as require special form of matrix, such as toys, clocks, &c., for an indefinite repetition of the same thing. The main utility of the phonograph, however, being for the purposes of letter writing and other forms of dictation, the design is made with a view to its utility for that purpose.

The general principles of construction are a flat plate or disk, with spiral groove on the face, operated by clock work underneath the plate; the grooves are cut very closely together, so as to give a great total length to each disk of surface—a close calculation gives as the capacity of each sheet of foil, upon which the record is had, in the neighborhood of 40,000 words. The sheet being but ten inches square, the cost is so trifling that but 100 words might be put upon a single sheet economically. Still, it is problematical whether a less number of grooves per inch might not be the better plan—it certainly would for letters—but it is desirable to have but one class of machines throughout the world; and as very extended communications, if put upon one sheet could be transported more economically than upon two, it is important that each sheet be given as great capacity as possible. The writer has not yet decided this point, but will experiment with views of ascertaining the best mean for capacity.

The practical application of this form of phonograph for communications is very simple. A sheet of foil is placed in the phonograph, the clock-work set in motion, and the matter dictated into the mouthpiece without other effort than when dictating to a stenographer. It is then removed, placed in a suitable form of envelope, and sent through the ordinary channels to the correspondent for whom designed. He, placing it upon his phonograph starts his clock work and listens to what his correspondent has to say. Inasmuch as it gives the tone of voice of his correspondent, it is identified. As it may be filed away as other letters, and at any subsequent time reproduced, it is a perfect record. As two sheets of foil have been indented with the same facility as a single sheet, the "writer" may thus keep a duplicate of his communication. As the principal of a business house, the particular now dictate the important business communications to clerk to be written out, they are required to do no more by the phonographic method, and do thereby dispense with the clerk, and maintain perfect privacy in their communications.

The phonograph letters may be dictated at home, or in the office of a friend, the presence of a stenograph or not being required. The dictation may be as rapid as the thoughts can be formed, or the lips utter them.—The receiver may listen to his letters being read at a rate of from 150 to 200 words per minute, and at the same time busy himself about other matters. Interjections, explanations, emphasis, exclamations, &c., may be thrown into such letters, silhitime.

In the early days of the phonograph, as it has become universally adopted, a correspondent in Hong Kong may possibly not be supplied with an apparatus, thus necessitating a written letter of the old fashioned sort. In that case the writer would use his phonograph simply as a dictating machine, his clerk writing it out from the phonograph at leisure, causing as many words to be uttered at one time as his memory was capable of retaining until he had written them down. This clerk need not be a stenographer, nor need he have been present when the letter was dictated, &c.

The advantages of such an innovation upon the present, slow, tedious, and costly methods are too numerous, and too readily suggest themselves to warrant their enumeration, while there are no disadvantages which will not disappear coincident with the general introduction of the new method.

Dictation.—All kinds and manner of dictation will partake of the application of the mouth of the speaker to the mouthpiece of the phonograph may be as readily effected by the phonograph as in the case of letters. If the matter is for the printer, he would much prefer, in setting it up in type, to use his ears in lieu of his eyes. He has other use for them. It would be even valuable to compel witnesses in court to speak directly into the phonograph, in order to thus obtain an unimpeachable record of their testimony.

The increased delicacy of the phonograph, which is in the near future, will enlarge this field rapidly. It may then include all the sayings, of not only the witness, but the judge and the counsel. It will then also comprehend the utterances of public speakers. * * *

Books.—Books may be read by the charitably inclined professional reader, or by the readers especially employed for that purpose, and the record of such book read in the sayings of the blind, the sick chamber, or even with great profit and amusement by the lady or gentleman whose eyes and hands may be otherwise employed; or, again, because of the greater enjoyment to be had from a book when read by an elocutionist, than when read by the average reader. The ordinary record sheet, repeating this book from 60 to a 100 times as it will, would command a price that would pay the original reader well for the slightly increased difficulty in reading it aloud in the phonograph.

Educational Purposes.—As an elocutionary teacher, or as a primary teacher for children, it will certainly be invaluable. By it, difficult passages may be correctly rendered for the pupil but once, after which he has only to apply to his phonograph for instructions. The child may thus learn to spell, commit to memory a lesson or for it, &c.

Music.—The phonograph will undoubtedly be liberally devoted to music. A song sung on the phonograph is reproduced with marvellous accuracy and power. Thus a friend may in a morning call sing, as a song which shall delight an evening company, &c. As a musical teacher it will be used to enable one to master a new air, the child to tone its first songs, or to sing him to sleep.

Family Record.—For the purpose of preserving the sayings, the voices, and the last words of the dying member of the family—as of great men—the phonograph will unquestionably outrank the photograph. In the full multiplication of original matrices, and the indefinite repetition of one and the same thing, the successful electrotyping of the original record is an essential. As this is a problem easy of solution, it properly ranks among the probabilities. It comprehends a vast field. The principal application of the phonograph in this direction is in the production of

Phonographic Books.—A book of 40,000 words upon a single metal plate ten inches square thus becomes a strong probability. The advantages of such books over those printed, are too readily seen to need mention. Such books would be listened to where now none are read. They would preserve more than the mental characteristics of the brain of the author; and as a bequest for future generations, they would be unequalled. For preservation of languages they would be invaluable.

Clocks.—The phonograph clock will tell you the hour of the day, call you to lunch, send your lover home at 10, &c.

Speech and other Utterances.—It will henceforth be possible to preserve for future generations the voices as well as the words of our Washingtons, our Lincolns, our Gladstones, &c., and to have them give us their "greatest efforts" in every town and hamlet in the country upon our holidays.

Lastly, and in quite another direction, the phonograph will perfect the telephone and revolutionize present systems of telegraphy. That useful invention is now restricted in its field of operation by reason of the fact, that it is a means of communication which leaves no record of its transactions, thus restricting its use to simple conversational chit-chat, and such unimportant details of business as are not considered of sufficient importance to record. Were this different, and our telephone conversation automatically recorded, we should find the reverse of the present status of the telephone. It would be expressly resorted to as a means of perfect record.

"How can this application be made? will probably be asked by those unfamiliar with either the telephone or phonograph.

Both these inventions cause a plate or disk to vibrate, and thus produce sound waves in harmony with those of the voice of the speaker. A very simple device may be made by which the one vibrating disk may be made to do duty for both the telephone and the phonograph, thus enabling the speaker to simultaneously transmit and record his message. What system of telegraphy can approach this? A similar combination at the distant end of the wire, enables the correspondent, if he is present, to hear it while it is being recorded. Thus we have a mere passage of words for the action, but a complete and durable record of these words as the result of that action.—Can economy of time or money go further than to annihilate time and space and bottle up for posterity the mere utterance of man, without other effort on his part than to speak the words?

In order to make this adaptation, it is only requisite that the phonograph shall be made slightly more sensitive in record, and the telephone very slightly increased in the vibrating force of its receiver, and it is accomplished. Indeed, the "Carbon Telephone," invented and perfected by the writer, will already well nigh effect the record on the phonograph: and as he is constantly improving upon it, to cause a more decided vibration of the plate of the receiver, this addition to the telephone may be looked for coincident with the other practical applications of the phonograph, and with almost equal certainty.

The telegraph company of the future—and that no distant one—will be simply an organization having a huge system of wires, central and sub central stations managed by skilled attendants, whose sole duty it will be to keep wires in proper repair, and give, by switch or alarm arrangement, proper attention to subscriber No. 223 in New York when he signals his desire to have private communication with subscriber No. 1001 in Boston for three minutes. The minor and totally inconsequent details which seem to arise as obstacles in the eyes of the groove traveling telegraph man, wedded to existing methods, will wholly disappear before that tremendous Juggernaut, "the needs of man;" for will not the necessities of man surmount trifles in order to reap the full benefit of an invention which practically brings him face to face with whom he will, and, better still, doing the work of a conscientious and infallible scribe?

THOMAS A. EDISON.

Mr. Edison has patented an arrangement which it is found to supersede the screw-machine in time. Screws are manufactured in great number and with great rapidity, and the machine is also said to be cleaner and more exact. The editor is the most noted of Mr. Edison's inventions. It saw action, as great.—*Cincinnati Times.*

CHRONIQUE

LE LIVRE D'OR DES ENTREPRENEURS.

Permettez-moi, chers lecteurs, et comme préambule, de vous donner connaissance des documents ci-après :

Les ministres des travaux publics,

Vu le paragraphe 2 de l'article 39 du règlement de comptabilité du 18 décembre 1877 contenant les dispositions suivantes :

« Les adjudications publiques relatives à des fournitures, à des travaux, à des exploitations ou fabrications qui ne peuvent être livrées sans inconvénient à une concurrence illimitée, sont soumises à des restrictions qui n'admettent à concourir que des personnes reconnues capables par l'administration et produisant des garanties exigées par les cahiers des charges. »

Considérant qu'il est de l'intérêt commun de l'Etat et des entrepreneurs que le choix des concurrents à admettre aux adjudications restreintes définies ci-dessus, soit entouré de toutes les garanties désirables ;

Arrêtent :

Art. 1er. — Il est institué une commission chargée d'examiner l'honorabilité, la solvabilité et la capacité des entrepreneurs qui se présenteront pour prendre part aux adjudications restreintes, du service des bâtiments civils et des palais nationaux.

Art. 2. — Cette commission est composée :

Du secrétaire général du ministère des travaux publics, président ;

Du directeur des bâtiments civils et des palais nationaux, vice-président ;

D'un délégué du tribunal de commerce ;

D'un délégué de la Banque de France ;

D'un délégué de la préfecture de police ;

D'un délégué de la préfecture de la Seine ;

D'un inspecteur général des ponts-et-chaussées ou d'un ingénieur en chef ;

D'un inspecteur général ou d'un architecte des bâtiments civils et des palais nationaux.

Les deux contrôleurs principaux attachés à la direction des bâtiments civils et palais nationaux remplissent les fonctions de secrétaires de cette commission, avec voix consultative.

Art. 3. — Cette commission dressera, dans la deuxième quinzaine du mois de mars, juin, septembre et décembre, la liste des entrepreneurs admis à prendre part aux adjudications pendant le trimestre suivant.

Les entrepreneurs qui désireront être admis seront tenus d'en faire la demande dans la première quinzaine des mois ci-dessus indiqués, en joignant à leur demande le certificat exigés par l'article 3 du cahier des charges générales.

Les entrepreneurs seront informés de la décision intervenue sur leur demande ; ceux dont le concours n'aura pas été accepté, pourront retirer immédiatement leurs certificats.

Art. 4. — Les dispositions du cahier des charges générales qui pourraient être contraires au présent arrêté, seront considérées comme de nul effet.

Versailles, le 9 avril 1878.

C. de Freycinet.

Ce qui précède ne nous prouve-t-il pas, dans une certaine mesure, qu'à la suite des abus qui se sont produits et se produisent encore journellement, il est devenu nécessaire pour tous, d'être à l'avenir renseigné sur le plus ou moins de capacité et d'honorabilité des entrepreneurs que nous sommes appelés à occuper, et que, lorsque le conseil de la Société nationale des architectes de France a, pour son usage personnel et celui de tous les membres de la Société, jugé opportune la création d'un livre d'or des entrepreneurs, il avait frappé juste.

Est-ce que ce que vise en grand l'arrêté précité n'est pas, dans une mesure plus modeste, aussi complètement utile.

Lorsqu'il y a trois mois, le conseil de la Société nationale des architectes approuvait la création du livre d'or des entrepreneurs, dont le but est tout autre retracé dans l'arrêté ministériel du 9 avril, n'allait-il double vue et pensait-il qu'en haut lieu on s'occupait d'établir les bases d'une commission d'enquête devant arriver au même résultat que celui qu'il se proposait d'obtenir.

Et cependant, un journal spécial, des plus sérieux même, tournait presque en ridicule, avec beaucoup d'esprit, je dois le reconnaître, la décision du conseil de la Société nationale et demandait même, s'il lui restait mémoire, comment la Société s'en tirerait si un entrepreneur se sachant inscrit commettait sur son livre d'or, venait attaquer la Société comme nuisant à son honneur et à sa considération.

Est-ce que ce n'est pas de bonne guerre? Comment, lorsqu'on n'est plus reçu aujourd'hui dans n'importe quelle société ou corporation sans un extrait du casier judiciaire, alors que société ou corporation s'engage cependant à bien peu, vous trouvez mauvais que, lorsqu'il s'agit de confier à un entrepreneur inconnu, des travaux importants et dont la plus ou moins bonne exécution peut entraîner la ruine de celui qui fait exécuter, on ne s'entoure pas de toutes les garanties morales, on ne recueille pas tous les renseignements commerciaux possibles. Alions donc ! C'est inadmissible.

Il devient, au contraire, en présence des rabais insensés, et disons-le, malhonnêtes qui se font aujourd'hui, et grâce auxquels des entrepreneurs inconnus et insolvables obtiennent des affaires qu'ils n'arrivent pas à terminer, de prendre au préalable toutes les entreprenons toutes les mesures que prescrivent la conscience et la dignité. Et lorsque, pour y arriver, ceci dans un cercle plus restreint, on n'a pas le pouvoir de promulguer d'un arrêté comme celui du 9 avril, il faut bien se défendre comme on peut, et, à défaut de commission d'enquête, se constituer un livre de renseignements.

J'attends la démonstration du contraire.

Léon Dumbeuil.

Reproduction interdite sans autorisation préalable.

de la part de M. Salleron.

commerçants.

Lecture de la correspondance. — Le Conseil met à l'ordre du jour la question des brevets d'invention et des marques de fabrique.

M. Jammet donne un rapport très-étendu sur cette question, qui a déjà été l'objet de plusieurs séances. Le Conseil, après avoir entendu les observations de M. Jammet, adopte les conclusions de son rapport, qui sont favorables à la prorogation des brevets d'invention et à la création d'un timbre spécial pour les marques de fabrique.

Le Conseil reçoit communication d'une lettre de M. Chaperon, maire d'Alger, qui demande l'appui du Conseil pour obtenir l'établissement d'un bureau de poste à la Maison-Carrée. Le Conseil, sur la proposition de M. Salleron, appuie cette demande auprès de M. le ministre du commerce.

Le Conseil, sur la proposition de M. Salleron, appuie également auprès de M. le ministre du commerce la demande de M. Chaperon, maire de Mustapha, tendant à obtenir l'établissement d'un bureau de poste à Mustapha-Supérieur.

M. Jammet donne un rapport très-favorable sur la demande de M. Bonnet, tendant à obtenir l'établissement d'un bureau de poste à Saint-Eugène

était si difficile de produire. Le papier d'étain est comme suspendu au-dessus du vide formé par le pas de vis tracé sur le cylindre ; il présente une certaine rigidité à cause de sa tension, mais, comme il n'est pas soutenu par derrière, il présente en même temps une certaine flexibilité. Grâce à ces propriétés, la feuille d'étain est capable, d'abord, de recevoir les impressions qu'y fait le style inscripteur, et ensuite de les rendre à la membrane quand on fait passer une seconde fois le style devant la feuille écrite. Le papier d'étain n'est pas encore, pensait-il, ce qu'il y a de mieux pour cet usage ; M. Edison emploie maintenant des feuilles de cuivre, sans doute de cuivre rouge, très-minces et qui donnent les meilleurs résultats.

Nous avons supposé implicitement dans ce qui précède que la rotation du cylindre était uniforme; mais il est clair que le mouvement donné directement par la manivelle ne peut pas être parfaitement régulier. Pour atténuer ce défaut, on a mis à la seconde extrémité de l'axe un lourd volant V, montré sur notre figure, qui, dans une certaine mesure, corrige les diverses variations de vitesse produites par l'action de la main. Il est facile de comprendre des appareils d'horlogerie, grâce auxquels on obtiendrait un mouvement uniforme ; c'est un point sur lequel il n'y a pas à insister.

Quand il s'agit de reproduire des paroles articulées par la voix humaine, les inégalités de vitesse sont de peu de conséquence ; le son monte ou baisse légèrement, selon que le cylindre se hâte ou se ralentit. Mais quand on reproduit des sons musicaux, le défaut est plus sensible. On [illegible]

do, sur le cylindre, on le rendra juste, à la condition qu'on tourne tout à fait régulièrement, et pendant l'inscription et pendant la reproduction du son ; mais pour peu que la vitesse n'ait pas été uniforme l'une des deux fois, l'accord n'est pas juste.

On peut noter ici en passant que, avec le téléphone les sons musicaux sont plus aisément rendus que les articulations de la voix ; aussi que avec le phonographe, tel que nous l'avons entendu, c'est l'inverse.

Mais l'avons dit et nous ne pouvons que le répéter ; ces petites imperfections de détail seront corrigées par des appareils donnant un mouvement très-régulier. D'autre part, M. Edison a récemment annoncé à Europe qu'il était arrivé à reproduire exactement le timbre de la voix humaine. Ce serait une nouvelle merveille ou plutôt un parachèvement d'une merveille mécanique ; mais dès à présent on ne saurait trop admirer le résultat obtenu et la simplicité extraordinaire des moyens mis en œuvre pour l'obtenir.

Parmi les perfectionnements qui ont été déjà réalisés, disait-il, par M. Edison, nous en indiquerons un seul. Dans de nouveaux appareils, le papier d'étain ne place non plus sur un cylindre, mais sur une plaque dans laquelle on a tracé une rainure qui a la forme d'une spirale d'Archimède, ou, pour parler le langage vulgaire, la forme d'un limaçon ; le mouvement de cette plaque est combiné de manière que le style porté par la membrane trace ses inscriptions dans la rainure de la spirale. Cette disposition est certainement plus compliquée que celle qui a été montrée à Paris ; mais elle permet de placer plus aisément et plus promptement la feuille d'étain et surtout elle permet, la feuille une fois écrite, de la placer sur un autre appareil qui fera la reproduction ; ce second appareil pourrait être dans une autre ville du monde que le premier.

C'est dans ces conditions qu'il sera possible à la Société française de physique d'entendre une communication verbale de M. Edison, communication qui aura été confiée à l'étain quinze jours auparavant et qui aura passé l'Atlantique dans une enveloppe de lettre. Cette chose extraordinaire n'a pas encore été réalisée, mais elle le sera certainement pour peu que M. Edison veuille continuer de suivre la voie dans laquelle il est entré si brillamment.

Ajoutons en terminant que le phonographe peut être combiné avec le téléphone, et sans parler de ce qui pourra être fait, disons que des expériences ont été exécutées cette semaine à Bruxelles dans lesquelles la membrane du phonographe était mise, au moment de la reproduction, en présence d'un aimant de téléphone. Les vibrations produites dans la membrane par le style, commandé par la feuille d'étain préalablement écrite, déterminaient des courants d'induction téléphonique dans le fil qui entourait l'aimant et se trouvaient reproduites dans un téléphone récepteur placé à distance.

Bien d'autres expériences de cet ordre sont possibles, mais ce n'est pas ici le lieu de laisser courir notre imagination. Contentons-nous d'avoir fait connaître des choses que les gens les plus autorisés regardaient comme irréalisables, il y a peu de temps encore. Sachons nous étonner, sachons jouir de la surprise et envoyons tous nos compliments admiratifs à l'heureux et persé-
